Rarely, if ever, has an entire people had more than enough to eat for any prolonged period of time. As a result, throughout history, as in many underdeveloped areas today, obesity has been restricted to the privileged classes. In many cultures it is a status symbol, and the legendary yearly weighings of the Aga Khan suggest that the size of its leaders can

FIGURE 1. This chart shows the decreasing prevalence of obesity with increasing socioeconomic status (S.E.S.) among women in a large American city. (From Goldblatt, P. B., Moore, M. E., and Stunkard, A. J. Social factors in obesity. *J. A. M. A.*, 192: 1039, 1965.)

TABLE I
Comparison of Obese and Normal People
on Mental Health Indices

Obese persons show a higher prevalence of neurotic traits and symptoms than nonobese members of the same population. Detailed analysis of these data, controlled for age and socioeconomic status, reveal that the differences are statistically significant.

Trait	Percentage Making Pathological Scores	
	Obese	Normal
Immaturity.....	63	49
Suspiciousness.....	43	25
Rigidity.....	67	45
Frustration-depression.....	23	18
Withdrawal.....	40	30
Tension-anxiety.....	34	31
Neurasthenia.....	17	10
Psychiatrists' rating.....	30	22
Childhood anxiety.....	32	38

represent a source of pride for an entire community. Under the circumstances, one might expect obesity to be more prevalent among the privileged groups. Recent studies in Germany and India support less systematic impressions from a number of cultures that this is indeed the case.

In the United States just the opposite situation prevails. Here, increase in socioeconomic status is associated with a *decreasing* prevalence of obesity. In one study the condition was six times more common among women of low status than among those of high status (see Figure 1). Social class of origin showed almost as strong an association, indicating that social class influenced obesity and not vice versa. The consistency with which social factors were associated with obesity indicates their profound importance in our understanding of it. In addition to social class, such factors include social mobility, ethnic and religious variables, and familial generation in the United States.

Age is the second major influence on obesity from the epidemiological point of view, with the prevalence of overweight more than doubling between the

ages of 20 and 50. Since the percentage of body weight composed of fat increases with increasing age, the influence of age on *obesity* is even greater than is indicated by the figures on *overweight*.

Etiology

The days when one expected to find *the* cause of obesity are long past, and the condition is currently viewed as the end product of a disturbance in energy balance. According to this view, human obesity consists of many different disorders, which can result from a variety of determinants acting singly, in combination, or through each other. Two such determinants, age and social factors, have been described above. Several others have been identified.

Physical factors. Genetic factors have been abundantly demonstrated in obesity among lower animals and must be presumed to be of importance in man, even though they have been demonstrated until now only in rare conditions, such as the Laurence-Moon-Biedl syndrome. Biochemical factors contribute to some forms of experimental obesity and probably do so in obesity in man, although evidence is so far lacking. Constitutional factors, such as body build, have interesting associations with obesity. Obese adolescent girls show extremely low ratings for ectomorphy, and the presence of even a medium degree of ectomorphy appears to protect against the development of obesity. Another study using the Kretschmerian typology found that rapid weight fluctuations and emotional disturbance occurred more frequently among obese persons of the adiposedyplastic type than among obese persons of the pyknic or pyknoathletic types.

Emotional factors. These are probably of great importance. First, many obese persons report that they overeat when they are emotionally upset. Second, obese persons are more likely to manifest neurotic traits and symptoms than are nonobese persons (see Table I).

It has proved singularly difficult to proceed from these simple and provocative findings to a more precise understanding of emotions and obesity. Much of the higher prevalence of neurotic traits and symptoms among obese persons, for example, is due to the overrepresentation of both neurotic traits and obesity among persons of older age and lower socioeconomic status. When both age and socioeconomic status are held constant, the difference between obese and non-obese persons becomes considerably less, although still statistically significant.

Kaplan and Kaplan have reviewed the many attempts to define an emotional constellation specific for overeating and obesity. Countless psychic impulses, symbolic meanings, conflicts and dynamics, particularly orality and pathological dependency, have been proposed. The very diversity of these factors argues against the existence of any one which operates in all cases of obesity. Carefully controlled studies have failed to uncover a specific personality

profile of obese persons or a psychodynamic conflict specifically related to their overeating. The most clear cut evidence of the influence of emotional determinants on obesity has been found in two small subgroups of obese persons, each characterized by an abnormal, stereotyped pattern of food intake.

The "night-eating syndrome," found in 10 per cent of obese persons, more commonly among women, is characterized by morning anorexia, evening hyperphagia, and insomnia. There is no apparent symbolic meaning of either the evening hyperphagia or the morning anorexia, nor is there self-condemnation related to the overeating. The syndrome is precipitated by stressful life situations, and, once begun, it tends to recur daily until alleviation of the stress. Attempts at weight reduction when the syndrome is present have an unusually poor outcome, and persons suffering from it are difficult to influence by psychotherapy.

The "binge-eating syndrome," found in less than 5 per cent of obese persons, is characterized by the sudden, compulsive ingestion of very large amounts of food in a very short period of time, usually with great subsequent agitation and self-condemnation. It, too, represents a reaction to stress. In contrast to the night-eating syndrome, however, bouts of overeating are not usually periodic. They tend to be far more closely linked to specific precipitating circumstances, sometimes occurring within minutes of a particularly frustrating experience. Binge eaters can sometimes lose large amounts of weight by rigid and unrealistic diets, but such efforts are usually interrupted by a resumption of the eating binges. The small percentage of obese persons who develop anorexia nervosa appear to have been binge eaters.

Some of the determinants of obesity may act through a decrease in physical activity, which results in a caloric surplus through two mechanisms—first, and most obviously, by a reduction in caloric expenditure, and second by its effects on appetite. Interestingly, in both animals and man, while appetite increases with energy expenditure over a wide range of energy demands, it does not decrease proportionally when physical activity falls below a minimal level. The restricted activity of many obese persons may thus actually *increase* their food intake! A measure of the extent of this restriction in one group is shown in Figure 2. The physical activity of obese women is so radically reduced as to account wholly for their obesity. Such radical restriction is not present among all obese persons. Among the men in the study, differences in physical activity were small, so that the additional energy expended by obese subjects in moving their heavier bodies produced a caloric expenditure equal to that of the nonobese men.

Related Disturbances

Some neurotic obese persons show disturbances in their body image involving one or two kinds of

FIGURE 2. Comparison of the physical activity of obese and nonobese men and women. Each point represents the average distance walked each day by each subject, as measured by a mechanical pedometer. Most obese women walked shorter distances than nonobese women. Among men, there is less difference in the distances walked. (From Chirico, A. M., and Stunkard, A. J. Physical activity and human obesity. *New Eng. J. Med.*, 263: 935, 1960.)

faulty perceptions: misperceptions of important visceral events and misperceptions of their physical appearance.

Misperceptions of visceral events. Some persons have difficulty in identifying hunger and satiety, and they frequently seem unable to distinguish between hunger and other kinds of dysphoria. This "conceptual confusion" has been linked by Bruch to severe deficits in identity and self-effectiveness and to the need for signals from the outside for a person to know when to eat and when to stop. A recent experimental analysis of such misperceptions indicates that they are due to a response bias that can be corrected by training procedures.

Misperceptions of physical appearance. An obese person's misperception of his physical appearance is usually confined to his obesity and is characterized by a feeling that his body is loathsome and grotesque and that others can view it only with hostility and contempt. Such preoccupations may color every personal relationship and make the person's body an explanation and a symbol of all his failures and disappointments. This latter type of misperception occurs only in persons who become obese before adult life, and adolescence is probably the critical period when it is imprinted.

Among persons who become obese as children, less than half develop body image disturbances. But in

this group, neurosis is closely linked to obesity, and it contains many if not most of the persons with night-eating and binge-eating syndromes. The poor prognosis in juvenile obesity, with more than 8 out of 10 obese children remaining obese as adults, suggests that obesity in children is potentially a very fruitful area for treatment and prevention.

Management and Prognosis

Weight reduction of obese persons is frequently successful when carried out in a hospital and usually unsuccessful when attempted on an out-patient basis. In both instances, successful dieters usually regain their lost weight in a short period of time. These poor results are due, in part at least, to the process of selection. Information about reducing diets is so widely available that only persons with great difficulty in losing weight seek medical treatment, and only the failures of medical treatment reach the psychiatrist. In view of this selection, it is understandable that there is no systematic evidence showing psychotherapy to be more effective than other, less expensive, aids to weight reduction. Not so understandable, in the absence of such evidence, is the widespread belief in the efficacy of psychotherapy, specifically in uncovering unconscious causes of over-eating. Efforts at such uncovering are usually fruitless and may produce overdependency on the therapist and inordinate regression. It is unlikely that psychotherapy can modify the symptom choice of persons who overeat as a response to stress. Years after successful psychotherapy and successful weight reduction, persons who overeat under stress continue to do so.

Despite these limitations, psychotherapy has a place in the management of obesity and an important place in the treatment of some carefully selected obese persons. As has been noted, many obese persons overeat when under stress. When they can be helped by psychotherapy to live less stressful and more gratifying lives, they are less apt to overeat and may lose weight, sometimes permanently. Such benefits are not less significant for being nonspecific results of treatment. Furthermore, two conditions may constitute specific indications for psychotherapy. Disturbances in body image and the binge-eating syndrome have been successfully treated, with enduring weight loss among the binge eaters. Neither condition is influenced by other forms of treatment, including, significantly, weight reduction. Psychotherapy of these conditions frequently requires years to ensure enduring results; it may be facilitated by modifications in technique designed to minimize intellectualization and regression.

Some patients are helped by participation in lay groups such as TOPS (Take Off Pounds Sensibly). Drugs are of limited value, and it is frequently desirable to try to protect patients from the alluring programs of quacks and promoters.

Serious emotional disturbances may occur among obese persons during attempts at weight reduction. Recent reports indicate that this complication is rarer than had been thought, and it need not preclude most weight reduction programs, but psychiatrists should be aware of its existence.

30.4 ANOREXIA NERVOSA

C. H. HARDIN BRANCH, M.D.

EUGENE L. BLISS, M.D.

A young woman thus afflicted, her clothes scarcely hanging together on her anatomy, her pulse slow and slack, her tem-

perature two degrees below the normal mean, her bowels closed, her hair like that of a corpse—dry and lustreless—her face and limbs ashy and cold, her hollow eyes the only vivid thing about her—this wan creature whose daily food might lie on a crown-piece, will be busy—yet on what funds God only knows.

This is a description by Allbutt and Rolleston of the severe form of anorexia nervosa, a disorder better designated as psychogenic malnutrition. The malnutrition is due to a voluntary reduction in caloric intake, unrelated to economic status or the availability of food. The usual patient eats parsimoniously and may consume less than 1,000 calories a day. Some patients curb an intense desire for food; others actually lose their appetites. There are those intent on being slim who induce vomiting, hide or dispose of food, or use cathartics. Whatever the technique, the final result is the same—a reduction in calories and consequent loss of weight. Weird though these strategies seem, they become reasonable when viewed from the perspective of the patient who is determined for personal reasons to lose weight or who is afraid to eat because food induces physical discomfort or intolerable fears.

Clinical Characteristics

There has been a misconception that only females suffer from this disturbance, but this is not true, since 10 per cent of the cases are males. In females amenorrhea is a frequent but not invariable finding, in some cases preceding the loss of weight, in others occurring only after significant malnutrition. Many patients have remarkable energy despite their cachexia; but some are initially neurasthenic, and all become feeble when weight drops to critical levels. Finally, constipation, hypotension, a mild anemia, and bradycardia are all features of the cachectic state, and each is attributable to the physiology of malnutrition.

The literature is laden with biases concerning the classification of these patients. Examination of a large number of cases, however, makes it clear that some patients are disturbed adolescents, and others are hysterical, obsessional, or schizophrenic. In fact, cases cover the entire range of the psychiatric nomenclature.

Different classes of patients usually become malnourished in distinctive ways. Typically, the adolescent anorexic patient worries about obesity and diets excessively to increase his or her self-respect and to escape ridicule. The hysterical patient develops somatic disturbances that interfere with the ingestion of food. The patient with a phobia fears obesity and refuses to eat, whereas the obsessional individual ruminates about food and obesity and pursues a ritualistic diet. The depressed patient loses his appetite and develops a disinterest in food, but the schizophrenic develops delusions about food and most typically decides it is contaminated or poisoned. A few rare females respond to pregnancy fantasies with anorexia and cachexia.

In many cases, food and body contours assume unusual symbolic significance. For example, to some obesity means voluptuous curves and sexually enticing

protuberances that are sources of shame. Others see leanness as a return to inconspicuousness or a regression to a childlike lack of responsibility. These attitudes, as well as other psychological sets, play important roles in many cases and lead to attitudes about leanness and food that motivate semistarvation.

Differential Diagnosis

Although, in the past, anorexia nervosa and panhypopituitarism were sometimes confused, they actually have little in common. In anorexia nervosa, adrenal cortical and thyroid functions are normal. A low basal metabolic rate reflects a hypometabolic state due to malnutrition that is unrelated to pathological thyroid function. The only endocrine disturbance is a reduction in gonadotropins associated with a drop in urinary estrogens. These last changes reverse when the malnutrition is corrected.

Malnutrition and anorexia are nonspecific symptoms that appear in a great number of infections, and in malignant and deficiency organic diseases. These must be ruled out in the differential diagnosis of anorexia nervosa.

Management

Treatment is based on the fact that anorexia nervosa is a symptom of a general psychiatric disorder. The therapy is, therefore, influenced by two considerations. (1) The malnutrition can usually be ignored unless the weight loss is excessive or sudden, in which case hospitalization and forced feeding may be required, since patients may die from severe malnutrition unless emergency action is taken. (2) The psychiatric treatment should be designed to assist the patient in attaining coping devices that are better than the neurotic misuse of food. The attack on the underlying psychopathology must be highly individualized, ranging from somatic modalities to psychoanalysis, depending on the case. A period of hospitalization can sometimes be used to give the patient a controlled environment where he can be separated from home and family.

Suggested Cross References

Anorexia nervosa is further discussed from the perspective of child psychiatry in Section 41.2. Fundamental concepts of the hunger drive are discussed by Malmo in Section 3.4, on motivation.

30.5 CARDIOVASCULAR DISORDERS

MORTON F. REISER, M.D.

Changes in cardiovascular function are an integral part of all emotional reactions. They may be extensive and profound, especially in severe anxiety states, and occur in acute, subacute, or chronic forms. As such, they represent a major component of the vegetative (neuroendocrine) response to psychological stress. Other components of the vegetative response involve metabolic pathways which may, in turn, influence the circulatory system through changes in water and electrolyte balance, blood fats, clotting mechanisms, etc. Accordingly, the relationships between psychopathological factors and cardiovascular pathology in the genesis of clinical disorders of the circulatory system may be exceedingly complex.

Heart Disease

Clinical features: General considerations. The symptoms (dyspnea, palpitation, tachycardia, substernal sensations of tightness or heaviness, perspiration, etc.) and signs (tachycardia, changes in blood pressure, perspiration, certain irregularities of cardiac rhythm, etc.) ordinarily associated with various forms of heart disease may also be observed in well developed anxiety states in the absence of underlying cardiovascular pathology. When acute states of this nature are recurrent and occur against a background of chronic low grade anxiety and tension, a number of diagnostic labels may be invoked. Actually, these conditions are best regarded and managed as anxiety states (acute, subacute, chronic, or mixed). However, in some cases the precordial sensations and symptoms become the primary focus of the patient's attention, and there is intense rumination and recurrent concern about heart disease which does not respond to ordinary techniques of direct reassurance. Such a condition might be labeled a "cardiac neurosis." The potential role of iatrogenesis in these cases is obvious, and the importance of prevention cannot be emphasized too strongly.

In another group of patients the predominant symptom complex may consist of more generalized complaints of chronic lassitude and weakness, with emphasis on faintness, excessive perspiration, and cold extremities (in addition to precordial and respiratory distress during acute anxiety attacks). This constellation has been labeled "neurocirculatory asthenia." Whether or not there are constitutional (metabolic) factors which would justify a separate diagnostic category for these patients is a matter of unsettled controversy at the present time.

The physiological changes brought about by anxiety and other activating affects, such as rage, must, of

course, be expected to exert important effects on the diseased cardiovascular system.

Psychophysiology in patients with structural heart disease. Under stress, the *diseased* cardiovascular system may not be capable of meeting the increased work demands that anxiety imposes and/or of maintaining its finely balanced regulating mechanisms within physiological limits under the impact of autonomic discharge and changes in levels and ratios of hormones, such as epinephrine and norepinephrine, to which it is exquisitely sensitive.

As demonstrated by Hickam, Cargill, and Golden, the burden imposed on the heart by anxiety is considerable, and comparable to that imposed by exertion. Whenever cardiac reserve is insufficient for performing the amount of work required to pump as much blood as the body requires, cardiac failure ensues. And it has been demonstrated by Chambers and Reiser that the increased work demanded by emotional stress may indeed lead to congestive heart failure in patients with severely diminished cardiac reserve. It appears possible that the increased work demand may well induce a state of relative functional coronary insufficiency in patients with coronary arteriosclerosis too severe to allow for enough increase in coronary blood flow to support increased myocardial work.

Psychophysiology of miscellaneous circulatory disorders. Regulatory cardiovascular functions which are finely balanced and sensitive to autonomic and hormonal changes include the mechanisms governing cardiac rate and rhythm, the caliber and tone of all components of the vascular tree, level of arterial blood pressure, and local perfusion of particular areas of the vascular bed (e.g., of various vital organs and extremities, etc.). Psychological stress may then precipitate and act as an aggravating factor in clinical disorders involving malfunction of these mechanisms, e.g., cardiac arrhythmias, migraine, essential hypertension, vasodepressor syncope, Raynaud's disease and other forms of peripheral vascular disease, coronary insufficiency, and cerebral vascular accidents. In some instances, the localization, anatomical or functional, of the disorder can be related to focal tissue pathology. For example, a rheumatic nodule or an ischemic scar involving a portion of the cardiac pacemaker-conduction system may provide a locus of irritability or refractory conduction that could account for development of a particular paroxysmal arrhythmia under the triggering influence of stress. In the absence of demonstrable local pathology, however, such an arrhythmia would be regarded as a psychophysiological cardiac reaction. Under such circumstances, it is not known what determines which area of the circulation or which of its functions will be involved (or, for that matter, whether the circulatory system will be the site of disease at all). The role of psychological mechanisms in respect to psychosomatic specificity is still a matter of controversy. Thus, it is not clear whether these mechanisms play any specific etiological role at

all and, if they do, whether they do so alone or in combination with other predisposing (e.g., constitutional) factors.

Psychological effects in patients with structural heart disease. The symptoms and diagnosis of heart disease may generate considerable initial (and often continuing) psychological distress for the patient. And the unresolved anxiety, somatopsychic in origin, may act to aggravate the condition or to counteract the effects of medical treatment. Cyclic self-reinforcing situations commonly develop. On the one hand, the mobilization of psychological defenses may be harmful; for instance, denial may lead to the patient's refusal to cooperate with the medical regimen. On the other hand, excessive invalidism out of proportion to the actual severity of the circulatory disorder may ensue and be severe enough to justify a diagnosis of cardiac neurosis.

The role and importance of direct verbal and non-verbal reassurance, sedation, and the judicious use of tranquilizing agents, particularly in acute situations, are obvious. Over the long term, these complicating psychological reactions may require the use of limited psychotherapeutic techniques (primarily proper management of the doctor-patient relationship) by the physician in charge. Occasionally, psychiatric consultation and treatment are required.

Hysterical conversion symptoms in patients with heart disease. Any of the symptoms of circulatory disease may occur as manifestations of major hysteria—that is, as conversion symptoms. Occasionally, patients who have an underlying cardiovascular disease and have experienced certain symptoms in association with it may subsequently experience the same symptoms on a purely psychological conversion basis in the absence of the concomitant physiological changes which previously gave rise to these symptoms. This possibility should be borne in mind in relation to patients with unaccountably intractable or recurrent symptoms, such as pain (angina), light-headedness, sense of breathlessness, and palpitation. Similarly, chronically recurrent symptoms of acute anxiety may eventually occur without physiological mobilization (e.g., palpitation without change in heart rate or stroke volume). When this situation obtains, it can be recognized by conducting the appropriate examinations or tests while symptoms are being experienced. If symptoms have become independent of their physiological background, treatment should be modified accordingly.

Possible psychological determinants of coronary heart disease. For many years there has been considerable interest in the possible role of psychological factors in the etiology of coronary heart disease. As noted above, emotional factors may contribute to the development of functional coronary insufficiency in patients with established coronary arteriosclerosis. However, the role of psychological factors in the etiology and pathogenesis of arteriosclerotic heart disease has not been clearly established. Formulations of

a "coronary personality" have not found consistent support in careful empirical research, although many investigators attribute this lack to the operation and complex interaction of multiple variables—such as age, sex, and socioeconomic status—which have not been fully taken into account in experimental design. Recent psychophysiological work suggests that emotional stress may be accompanied by changes in blood-clotting mechanisms and level of blood cholesterol, but, again, this awaits systematic replication and validation. Accordingly, it is probably best at this time to suspend judgment regarding the exact role of psychological factors in the etiology and pathogenesis of coronary heart disease.

Essential Hypertension

Essential hypertension is the term used to refer to the sustained elevation of systolic and diastolic arterial blood pressure in the absence of any of the demonstrable known causes of arterial hypertension.

Clinical features. The disease exists in two forms, benign and malignant, distinguished primarily by the extent of visceral (particularly renal) damage, rate of progression, and, to a lesser degree, the height of the patient's blood pressure, particularly the diastolic pressure. Usually, the malignant (accelerated) form is superimposed on a preexistent benign essential hypertension, but it may take this form from the outset, particularly in younger individuals. The disease manifests its damage through changes in the arterial tree, particularly the smaller arterial radicles and arterioles, which show a form of arteriosclerosis termed arteriolesclerosis. This condition is widespread but leads specifically to clinically important pathology in the heart, brain, and kidneys—the organs that are the three major sources of morbidity and death (in that order of frequency). The basic symptoms which are directly (and unquestionably) attributable to the disease are those associated with arteriosclerotic heart disease (congestive failure and/or coronary insufficiency), cerebral arterial disease (acute vascular accidents, thrombosis and hemorrhage, and acute hypertensive encephalopathy), and arteriolar nephrosclerosis (renal insufficiency and uremia).

The disease may, and usually does, run an indolent, benign course. The elevation of the blood pressure is thought to accelerate or aggravate the arteriosclerotic process; however, there is no absolute relationship between level of blood pressure and prognosis, although in general the trend is for higher blood pressure levels to augur more rapid progression of the disease process. Actually, this is difficult to evaluate because of the frequent artifact that the blood pressure level in patients with essential hypertension is extremely sensitive to circumstances of measurement. Thus, levels determined in the physician's office may be quite a bit higher than the patient's ordinary day-to-day blood pressure and hence not truly representative. In any event, there are many instances on record

where patients with quite high blood pressure levels have lived long, comfortable, and useful lives and have died of some other disease.

Nor is there a clear one-to-one relationship between blood pressure level and symptomatology. Although patients with the disease may experience many symptoms often attributed to hypertension—such as headache, dizziness, light-headedness, breathlessness, precordial tension, lethargy, lassitude, easy fatigability, muscle cramps, etc.—many physicians now regard such symptoms as primarily psychological in origin. Furthermore, the benign form of the disease may be quite asymptomatic; as a matter of fact, it is often discovered in the course of a routine examination with some evidence—in the eyegrounds, for instance—that it has existed without symptoms for some time.

The basic pathological physiology of the elevated (systolic, diastolic, and mean) arterial blood pressure consists of an increased peripheral resistance, which is due primarily to a decreased total cross-sectional area of the arteriolar bed. Cardiac output (stroke volume and heart rate), blood viscosity, etc., are within normal limits during the uncomplicated phases of the disease. The narrowing of the total arteriolar cross section may result from functional (reversible) increase in the tone of the arteriolar walls and from structural (irreversible) arteriosclerotic changes. The former may be mediated through sympathetic nervous system pathways, through the effects of circulating pressor substances, or through combinations of the two.

Psychophysiology. Although this cardiovascular dynamic pattern can be produced and aggravated by psychological stress in the patient with essential hypertension (with a resultant rise in blood pressure), this is not the most common pattern of change in circulatory dynamics in normotensive individuals under psychological stress. The more common reaction in the nonhypertensive individual with anxiety is an elevation of systolic blood pressure, a fall in diastolic blood pressure (relatively unchanged or slightly lowered mean blood pressure), increased cardiac output (stroke volume and heart rate), and decrease in peripheral resistance. Occasionally, the hypertensive pattern or combinations of the hypertensive pattern and the pattern just described can be elicited in the normotensive individual in psychophysiological experimentation. But no clear cut, unequivocal differential relationship between specific affects, such as rage and anxiety, and specific patterns of cardiovascular dynamic change have been satisfactorily demonstrated in normotensive individuals as yet. On the other hand, the hypertensive mechanism—that is, spasm of the arterioles with increase in peripheral resistance—can be readily and reproducibly activated psychologically in the patient with essential hypertension. It has been demonstrated that these pressor responses may be mediated through both the neurogenic and the

humoral mechanisms which are known to affect arteriolar tone.

Psychological determinants. Innumerable clinical studies have demonstrated that the onset (or discovery) of the disease, occurrence of complications (heart failure, myocardial infarction, cerebral vascular accidents, hypertensive encephalopathy, etc.), and even acceleration of the disease from the benign to the malignant phase may occur in conjunction with the sustained emotional turmoil accompanying life crises. The external nature of these crises and the internal character of the patient's emotional turmoil are consistent within each patient, in accordance with his personality and life history. It has also been observed that frequently the progress of the disease is slow during periods when the patient's personal affairs are quiet and well ordered, and he is able to maintain a well ordered, "good" relationship with the physician.

Although no specific psychological characteristics distinguishing these patients as a group from the general population have been reliably established, a few very broad and nonspecific generalizations can be made about some psychological characteristics of patients with hypertension. Like other patients with major psychosomatic diseases, most often their core psychological conflicts are observed to center around pregenital libidinal issues and difficulties in the neutralization of aggression. In addition, they have particular problems in dependency relationships, in which they display extreme degrees of ambivalence (which often interferes with optimal management of the doctor-patient relationship, especially at times of crisis).

Although the role of the emotions as a major and highly important influence on the clinical course of essential hypertension has been clearly established, the mechanism and role of psychological factors in the etiology of the disease are not clearly understood. A great deal of research has been carried out on this question, however, and the evidence is suggestive (but not conclusive) that emotional factors may play some role in etiology, along with constitutional and possibly other, as yet unknown factors. A major multiple factor theory was proposed by Franz Alexander, who postulated a specific emotional problem (involving modulation and management of rage) as a necessary (but not sufficient) condition for the development of essential hypertension.

Treatment. A primary problem in the treatment of essential hypertension centers around the proper evaluation of the patient's clinical status and course and attainment of a clear perspective as to the nature and source of the patient's symptoms. Most medical authorities agree that major specific measures—hypotensive drugs, surgery, special diets, etc.—should be reserved until the disease shows signs of increased rate of progression. However, determination of the point where a previously indolent course is beginning

to show signs of progression is a judgment which often requires the utmost in clinical skill and acumen. This potentially critical development in the course of the disease is best detected through careful serial evaluation of the patient's cardiac and renal status and regular observation of the patient for the appearance and progression of the characteristic changes of hypertension in the optic fundi.

Perhaps the major contribution of psychiatric studies of this disease has been to clarify the limited significance of the level of blood pressure, *per se*, and to provide a clearer perspective for understanding the origin of symptoms.

The most frequent—and frequently the most difficult—psychological problem confronting the physician emanates from the patient's fear of the disease. To be effective, reassurance must be based on firm conviction which is valid in respect to the physician's knowledge of the natural history of the disease, and also based on careful appraisal of the patient's clinical status and thoughtful formulation of the mechanisms underlying his symptoms. Reassurance that stems from generalities rather than specifics, however well intended, is apt to be hollow and to backfire eventually. In most instances, the patient's fears far exceed the actual dangers of the situation, so that the physician has a great deal of leeway within which to take a realistically based position that is clinically sound and inwardly comfortable and permits consistency in his continuing long term management of the patient.

It is important to recognize those symptoms which are of neurotic origin for what they are, and to base such a diagnosis on careful study of the patient's personal history so that a positive psychiatric formulation can be made and substantiated. It is not sufficient to arrive at such a diagnosis simply by the process of exclusion. This is a course fraught with danger for the patient.

On the basis of his thorough and sober understanding of the patient, then, the physician can (1) avoid unnecessary and even harmful medications, treatment, restrictions, etc., and (2) apply appropriate (psychotherapeutic) treatment techniques. In general, the major psychotherapeutic tool available to the general physician in the management of the patient with hypertension is the doctor-patient relationship. Adjunctive use of psychoactive drugs should be considered in instances where the psychiatric clinical status of the patient provides appropriate indications. Additionally, these drugs may be prescribed for their tranquilizing, sedative, or antidepressant properties when it is felt that sustained emotional tension (anxiety and/or depression) may be aggravating the physiological disorder. Although some of the psychoactive drugs do exert effects on autonomic function, including a degree of inhibition of or interference with adrenergic sympathetic activity, such effects probably

do not, in themselves, constitute indications for use in the treatment of the patient with essential hypertension. The incidence of depression as an untoward side effect of long term Serpasil administration may be more commonly encountered in patients with essential hypertension than in patients with normal blood pressure.

In brief, each patient should be studied individually, and treatment should be based on the best understanding the physician can achieve in respect to his particular problems and situation, rather than on any preconceived "formula," such as the once popular notion that the patient with hypertension would be helped if he were encouraged to express his anger more freely. Appraisal of the advisability of undertaking specific modes of intensive psychotherapy should be based on the usual psychiatric indications without special qualifications related to hypertension.

Vasodepressor Syncope

Syncope, or fainting, is due to acute peripheral circulatory inadequacy which is usually quickly reversible. The disorder may arise from a number of causes. Thus, vasodepressor syncope, which is its most common form, must be differentiated from carotid sinus syncope; from postural hypotension; from faints associated with cardiac, respiratory, and cerebral disorders; from faints that are primarily psychic in nature; and from epilepsy, narcolepsy, and catalepsy.

Clinical features. Vasodepressor syncope may occur under a wide variety of familiar circumstances, e.g., pain, anxiety, shock, etc., all of which share two characteristics in common. First, fear is a major component of each; second, as Engel has pointed out, they are all experienced in relation to some type of injury to the organism—whether actual, threatened, or fantasied. Pain, tissue damage, reduction in blood volume, peripheral vasodilation, and anoxemia are factors which may predispose to vasodepressor syncope and, when present, participate in the genesis of the attack.

The faint usually has its onset while the individual is in an erect position and is commonly preceded by manifest anxiety and a characteristic set of premonitory symptoms: sweating, nausea, restlessness, muscle weakness, pallor, and sighing. Often, the attack can be averted if the individual lies down when these premonitory symptoms appear. If this procedure is not followed, these symptoms may be followed within a few minutes by blurred vision, light-headedness, and, finally, loss of consciousness and falling. At the very beginning of the prodromal period, blood pressure and pulse may be elevated, but the faint itself is characterized by a rapid fall in arterial blood pressure, the fall in systolic pressure being somewhat greater than the fall in diastolic pressure. When systolic pressure falls to critical levels (55 to 60 mm. Hg), loss of consciousness occurs, and heart rate frequently slows abruptly to 30 to 60 beats per minute, reflecting some degree of

heart block mediated by the vagus nerve. At this point, there is a slowing of the brain waves to two to four per second. If the faint persists for more than 15 to 20 seconds, mild brief clonic convulsive movements may occur.

Psychophysiology. Engel has formulated the psychophysiological hypothesis that vasodepressor syncope occurs when the individual lacks the freedom to take appropriate action against his fear or anxiety. He hypothesizes that under such circumstances the circulatory preparation for action (fight or flight), which includes increased muscle blood flow, takes place but is not followed by action. Without activity, this redistribution of blood is not compensated for by muscle contraction, reflex increase in cardiac output, and vasoconstriction in other portions of the vascular bed. As a result, blood pressure falls, due to the pooling of blood in the muscle mass of the extremities, which remain immobile.

Since vasodepressor syncopal attacks are more apt to occur if fear must be denied, they tend to occur more often in men than in women in certain situations, such as venipuncture and threatened pain from medical and dental procedures. (It is well known that this type of fainting may even become "contagious" when a large group of men are being processed for Army service, for example.)

Treatment. Usually, the patient regains consciousness soon after he falls or is placed in a recumbent position, and circulatory and other physiological signs return to normal. Some of the premonitory symptoms may persist briefly, however, and the faint may recur if the patient sits or stands up too soon. Therefore, while the attack itself does not require special treatment, the patient should be encouraged to exercise his legs while he is still lying down and to move actively about after he rises until his circulation and blood pressure are stabilized.

If attacks of vasodepressor syncope are recurrent without demonstrable physical cause and adequate situational provocation, they should be regarded as clinical evidence of a neurotic disorder, and the patient should be treated accordingly.

30.6 RESPIRATORY DISORDERS

MARVIN STEIN, M.D.

RAUL SCHIAVI, M.D.

The primary function of the respiratory system is the intake of oxygen and the elimination of carbon dioxide. These processes, being vital to life, have a marked affective and symbolic significance. The respiratory system is closely related to a variety of behavioral activities that have considerable emotional meaning. Crying, sucking, smelling, and the expulsion of irritants by means of coughing and sneezing are all associated with respiration from the earliest moments of life. As the infant feeds, for example, there is close coordination of sucking, swallowing, and breathing. The respiratory system is involved in the earliest significant relationships that the individual has with other people and provides one of the earliest means of expressing emotional reactions and needs.

Considerable evidence indicates that the central nervous system (CNS), by means of pontine, diencephalic, and cortical mechanisms, regulates respiratory function. The close relationship between CNS activity and respiration affords a physiological basis for the

profound influences of psychological and emotional processes on respiration.

The relation between respiration and psychological and emotional experiences has been considered from both an experimental and clinical point of view. Early studies indicated that increased attention or mental work is accompanied by a decrease in respiratory amplitude and an increase in rate. Finesinger and Mazick studied the effect of the recall of pleasant and unpleasant ideas on the respiratory response of normal and neurotic subjects. Of the respiratory functions studied, the minute volume showed the greatest consistency of deviation in relation to changes in ideational stimulation. Most phobic patients and those with anxiety neurosis, and the majority of control subjects as well, showed a considerable increase in minute volume during unpleasant periods as compared with the pleasant ones. Essentially similar changes were found by Finesinger and Mazick in an analogous population during the actual administration of painful stimuli and again during subsequent recall of the experience. Other investigators have been interested in the relationship between psychodynamic patterns and respiration. Alexander and Saul, for example, analyzed respiratory tracings with special reference to psychological correlations and found suggestive evidence of a relation between emotional themes having to do with the ingestion, retention, and elimination of food and certain characteristics of the spirogram.

Hyperventilation

Anxiety and hyperventilation. Of all the affective experiences of man, anxiety is the most commonly experienced by all. Anxiety, in addition to its subjective component, is characterized by a variety of physiological reactions, such as pallor, blushing, quickened heart beat, and respiratory disturbances. One of the most common complaints of anxious patients is difficulty in breathing. Patients often demonstrate this by deep sighs or state that they cannot get enough air. The respiratory concomitants of anxiety are primarily ventilatory in nature and may vary in form from deep sighs or hyperventilation to breath holding. In an analysis of a large number of spiograms, Finesinger found that the incidence of sighing respiration was considerably higher in a group of patients suffering from anxiety than in a control population.

Clinical features. The hyperventilation accompanying anxiety is often called to the physician's attention by symptoms such as fainting or tingling of the extremities, which are due primarily to a decrease in blood carbonate. Engel et al. have studied the clinical aspects of hyperventilation of psychogenic origin. They divided the symptoms into those related to the reduction of consciousness and those related to tetany. Reduction in consciousness correlates with changes in the electroencephalogram, and tetany is unrelated to such changes. Reduction in consciousness is often associated with giddiness, faintness, light-headedness,

and blurring of vision; tetany appears only after longer periods of hyperventilation and is much less frequent.

Differential diagnosis. In the differential diagnosis of hyperventilation, it is important to consider other causes, such as febrile illnesses, high external temperatures, and at times encephalitis. Hyperventilation due to anxiety may be mistaken for asthma.

Treatment. In many cases the replication of the light-headedness, tingling, and faintness produced by requested hyperventilation serves as a source of reassurance to the patient. Psychotherapy is often effective in the treatment of the anxiety underlying the hyperventilation syndrome.

Asthma

The major psychophysiological respiratory disorder is bronchial asthma. Asthma can be broadly and simply defined as dyspnea with wheezing. The primary pulmonary change in asthmatic breathing is bronchial obstruction resulting from a combination of bronchospasm, bronchial edema, and mucous plugs. The obstructive processes produce the signs and symptoms.

Etiology. The investigation of bronchial asthma has been concerned with the role of allergic, infectious, psychological, social, endocrine, and hereditary factors. A specific etiological determinant has not been isolated. The most thoroughly studied mechanism has been hypersensitivity to allergens. Allergic asthma has been demonstrated experimentally as well as clinically in humans and animals, but it appears at the present time that a variety of factors are involved in the development of asthma and in the precipitation of asthma attacks.

Psychophysiological mechanisms. Psychological processes may be involved in the pathophysiology of asthma by means of several mechanisms. Emotions may modify the immunological or allergic mechanisms responsible for some cases of asthma, and emotional phenomena may also be related to the development of asthma by means of CNS control of bronchiolar function. A combination of both these processes in varying proportions occurs in many cases.

Allergic and immunological mechanisms. There is considerable clinical evidence that emotional factors modify some types of allergic disorders; however, until recently few experimental studies have considered the effect of psychological stress on immunological responses. Rasmussen et al. have demonstrated that mice subjected to a standardized avoidance conditioning stress show an increased susceptibility to herpes simplex virus and decreased susceptibility to passive anaphylaxis. Chronic avoidance conditioning was also found by Wistar and Hildemann to depress the immune reaction responsible for the rejection of skin homografts. A decrease in susceptibility to Type I polio virus has been observed in monkeys following an acute avoidance conditioning procedure. A number of reports in the Russian literature have considered the effect of psychological mechanisms on antibody titers.

Petrovski, for example, studied changes in agglutinin titers associated with behavioral disturbances induced in immunized dogs and baboons by stressful stimuli or by conflict conditioning techniques. He observed a parallelism between the intensity and duration of the behavioral disturbance and the fall in circulating antibody titers.

Recently the neurophysiological mechanisms that may mediate the psychological influences on immunological reactions have been experimentally studied. A growing body of literature indicates that CNS processes may modify hypersensitive mechanisms, specifically anaphylaxis. Freedman and Fenichel tested the effect of midbrain lesions on the course of anaphylaxis in the guinea pig and found that bilateral lesions in the midbrain reticulum at the level of the superior colliculus prevented anaphylactic death. Szentivanyi and Filipp have reported that lethal anaphylactic shock in the guinea pig can be prevented by focal lesions in the tuberal region of the hypothalamus. It has been shown by Luparello, Stein, and Park that anterior but not posterior hypothalamic lesions afford significant protection against lethal anaphylactic shock in the rat.

A variety of factors may be involved in the protective action of hypothalamic lesions on guinea pig and rat anaphylaxis. Hypothalamic neuroendocrine processes concerned with the control and release of adrenocorticotrophic hormone (ACTH) and thyroid-stimulating hormone may play a role. It has been shown by some but not all workers that ACTH and cortisone provide protection against guinea pig anaphylactic shock. Several investigators have reported that a close relationship exists between thyroid physiology and anaphylactic processes. Recent studies have suggested that the hypothalamus may also take part in the regulation of immune processes through autonomic nervous activity.

The protective action of hypothalamic lesions on the course of anaphylaxis may be related to an alteration in antibody production. Recent studies have suggested that the hypothalamus may participate in the mechanisms determining antibody level. The authors have found that lesions in the anterior hypothalamus are associated with a significant decrease in circulating antibodies in the guinea pig.

Bronchiolar function. Emotions and the CNS may also play a role in asthma by means of a direct effect on bronchiolar physiology independent of allergic mechanisms. It has been demonstrated by a number of investigators that stimulation of the vagus nerve produces bronchiolar obstruction. In 1887 Francois-Frank reported that electrical stimulation of the motor cortex can produce bronchoconstriction. However, relatively few studies have been concerned with the CNS control of airway caliber. The availability of techniques for the measurement of airway resistance and lung compliance provides the opportunity for

quantitative research on CNS control of airway caliber.

Personality patterns. The emotional factors involved in the development and precipitation of asthma have been considered from several standpoints. One of the earliest approaches was to investigate the relationship between asthma and personality patterns. A number of studies suggested a relationship between a cyclothymic or hysterical personality and asthma. A "respiratory personality" in asthmatics—characterized by a cyclothymic disposition associated with paranoid features, repressed hostility, and a desire for self-punishment—has been described. McDermott and Cobb, in a clinical survey of 50 cases of bronchial asthma, studied each case from a psychiatric point of view. They found that in 37 of the patients there was an emotional component in their asthmatic attacks. Furthermore, they reported that 30 of the 50 asthmatics showed neurotic traits predominantly of a compulsive character. This approach has led some investigators to classify asthmatic patients into an allergic group and a psychic group, but recent studies have found no convincing evidence to support this division. Current investigations have shown that there is a wide variation in personality disturbances among asthmatic patients, and there is no single personality type.

Psychodynamics. The attempts to discover a common personality type in asthma have given way to efforts to find a specific psychic constellation. In the psychoanalytic literature, a number of specific conflicts have been reported as leading to bronchial asthma. Some workers have been struck by the close relationship between asthma and fantasies associated with aggressive and especially anal soiling impulses. It has been suggested that the bronchiolar obstruction is an attempt to ward off retaliatory aggressive anal impulses. This notion is in keeping with Wolf's observations of defensive physiological reactions of the nose and respiratory system in response to irritants and unpleasant emotional stimuli.

Much of the recent emphasis on the psychological genesis of asthma has been concerned with the view that the significant psychodynamic process in asthma is unconscious fear of loss of the mother or mother figure. This was first suggested by Eduardo Weiss, who described the asthmatic attack as being similar to the "shrieking, helplessly sprawling newborn child with the blood-red swollen face."

French and Alexander reported a study of 27 asthmatic patients undergoing psychoanalytic treatment. They described the central emotional problem in asthma as a fear of separation from the mother and concluded that the asthmatic attack is equivalent to a repressed cry for the lost mother. Many investigators, including the authors, have come to the position that one of the most frequent psychodynamic themes in perennial asthmatic patients is an exaggerated need

for a bond with the mother or mother figure. This need is accompanied by an acute fear of loss of the mother's love, which may be mobilized by an actual physical separation or by situations that threaten estrangement from the mother.

It is in relation to an exaggerated need for love and the consequent fear of separation that the authors have noted a variety of situations and stimuli as antecedent events to an asthmatic attack. We have observed that sexual temptations, competitive feelings, narcissistic desires, and hostile impulses may precede asthmatic attacks. Our clinical experience suggests that behavior or fantasies with such themes become sources of emotional tension to the asthmatic because they stimulate fears of retaliatory withdrawal or estrangement from a parental figure.

The possibility must be raised that the dependency observed in asthmatics may not be primary but secondary to the disease process. The asthmatic attack itself could give rise to an acute need to cling to a mother figure and may, therefore, tend to reinforce the helpless dependency seen in these patients. Only further research will provide an answer to this important question.

Learned determinant. The conditioned reflex also has been suggested as one of the psychological mechanisms involved in asthma. Many clinical papers have reported that stimuli regularly associated with the presence of an allergic substance may precipitate an attack in a susceptible individual. For example, an artificial rose may precipitate an attack in an individual allergic to rose pollen. Conducting allergic studies with humans, Herxheimer observed that, when asthmatic subjects are merely placed in a situation in which on repeated occasions they have been previously exposed to allergens, many develop asthma without the exposure. Dekker, Pelser, and Groen have reported conditioned asthmatic attacks in a laboratory setting. They followed a procedure similar to Herxheimer's, using a known allergen paired with neutral solvents and found in two subjects after repeated trials that the inhalation of pure oxygen caused attacks of asthma, as demonstrated by clinical signs and changes in vital capacity. The mouthpiece alone was eventually sufficient to cause an attack. These attacks could not be distinguished from those that appeared after allergen exposure. Recently, Ottenberg et al. and Noelpp and Noelpp-Eschenhagen have reported that a respiratory response similar to asthma can be conditioned in the guinea pig.

It has been demonstrated by Schiavi, Stein, and Sethi that it is possible to produce in the guinea pig, in response to a pain-fear stimulus, an asthmatic-like respiratory pattern—shortened inspiration and prolonged expiration—without evidence of bronchiolar obstruction. This was in contrast to the findings in guinea pig experimental asthma of an identical respiratory pattern but with the presence of bronchiolar ob-

struction. Humans also may develop an asthmatic-like respiratory pattern during hyperventilation without concomitant changes in bronchiolar physiology. The above findings suggest that it is important to define asthma in terms of bronchiolar function as well as the usual ventilatory variables. Such respiratory criteria will permit precise evaluation of psychological factors that may play a role in bronchial asthma and provide aid in the differential diagnosis and treatment of the disorder.

Treatment. As indicated in the above discussion, many factors are involved in the development and precipitation of asthma. Therefore, in the treatment a collaborative approach is often required. The joint efforts of the internist and psychiatrist are important in the handling of the medical and psychological aspects of the illness. From a psychiatric point of view, the treatment may range from supportive to intensive insight forms of psychotherapy. In each it is necessary to have an adequate understanding of the physiology and psychodynamics involved.

30.7 SEXUAL POTENCY DISORDERS OF THE MALE

DONALD W. HASTINGS, M.D.

Sexuality is a highly emotional and ubiquitous human experience. A wide variation in sexual practices and frequency falls within the limits of normality. According to Kinsey, male sexuality reaches its frequency peak in adolescence and declines steadily from then on; he estimates the number of sexual acts performed by a male may reach 100,000 in his lifetime.

Sexual functioning in the human male represents a dynamic interaction between psychic and somatic determinants. Sexuality is influenced by complex conscious and unconscious psychic factors, by such physiological factors as neurological and endocrine status and age, and by such sociocultural factors as income and education and the prevailing sexual mores and attitudes about women. The sexual process is sensitive and may be disturbed by any one of these factors. Sexual disturbances are prevalent in our culture. Impotence and premature ejaculation are the most common sexual complaints of males.

Impotence

Impotence may be defined as that condition wherein the male cannot obtain or maintain an erection satisfactory to him for purposes of heterosexual coitus. It is a relatively common condition at all ages but is a particularly distressing one in the younger years of adult life. As Stokes pointed out, "Among civilized peoples there are many cases of unresponsiveness at the peak of adult vigor. This is an anomaly in the biological world."

Etiology. In bygone years, there were numerous speculations about the causes of impotence, most of which had to do with the aging process in the geriatric period or with organic factors in the younger age groups. One of the most persistent of the latter ideas was that impotence was due to inflammation of the posterior urethra at the site of the verumontanum. A favorite treatment was to paint this area with

a silver nitrate solution. This concept became untenable in more recent years, when studies showed that males with severe inflammatory lesions of the posterior urethra—due to gonorrhea, for example—were usually not impotent at all. If such inflammatory lesions of the urethra produced impotence, gonorrhea would be much less of a public health problem than it is.

Psychological factors in the etiology of impotence and its analogous situation in the female, frigidity, had been described decades ago by Freud and Stekel, but these concepts were, for the most part, accepted only slowly by the medical profession. Today, students of these conditions agree that the vast majority of cases are due to psychological factors, although it is true that some are due to other determinants. From an etiological standpoint, impotence can be classified as due to (1) organic disease, (2) drugs, and (3) psychological factors. Effective treatment depends on the accurate diagnosis of the underlying cause.

Organic disease

Systemic disease. Any physical disease that produces weakness and malaise understandably interferes with sexual drive and arousal during its course. This is so obvious that it needs no exposition. The problem that arises in this context is the systemic disease that is vague or undiagnosed. It is stated by numerous authorities that impotence frequently accompanies diabetes mellitus and, in fact, may be one of the earliest symptoms. The reasons for such a relationship are not clear. It is said that potency usually returns when the diabetes is brought under control. Hypothyroidism, anemias, and malnutrition have also been mentioned as etiological factors.

Aging. Although the aging process is not a disease as such, its effect on potency is considered here. It is a common belief that the older the man, the less potent he is. Kinsey et al. found that impotence increases with age, with practically no men in their sample impotent at age 35, and 77 per cent impotent at 80. They note the phenomenon of wide individual differences and report erections and coitus in some males of advanced age. Although sexual activity, like most other activities, shows a decline as the years advance, it is not correct to assume that impotence is an inevitable function of advanced years. Studies by Finkle et al. and Newman and Nichols indicate that marital status—that is, having an available sexual partner—is more closely related to continuing potency in the aging male than is age per se. These authors concluded that the older single male—the widower, for example—often lacks the drive and interest required to seek a sexual partner and thus reports that he is impotent, whereas the married older male is often able to continue coitus into advanced years. The latter authors made the interesting point that "One commonly recognized belief among younger people in our society is

that older persons, especially grandparents, have no sexual feelings," and then went on to give their data, which show how wrong this concept is. In our society, the probability is that the amount of sexual activity engaged in by older persons is more a function of a readily available sexual partner than it is a function of age alone.

Local disease. Castration is a possible cause of impotence, although it does not uniformly result in impotence. Rowe and Lawrence reported the case of a castrated man who carried on satisfactory marital relations for 25 years. McCartney observed 10 cases of gonorrhea in 23 eunuchs he studied. Tauber gave an historical review of the topic and noted that the changes in potency after castration are unpredictable. He raised the question of whether castration per se interferes with the sexual life by stopping a biological requirement or whether interference with potency, if it develops, may not be on a psychological basis. There is much clearer agreement that the cessation of ovarian function, whether by surgical removal or as a result of the menopause, does not interfere with the previously established sexual pattern of the adult female. However, there is evidence to suggest that androgens—from the adrenal gland in men and women—may be an important determinant of male and female sexual drive.

Prostatic disease and prostatectomy. There appears to be agreement in the medical literature that prostatic disease, whether infectious or neoplastic in nature, does not result predictably in impotence unless the lesion produces pain. In this regard it can be interfering. The effect of prostatectomy on potency is not clear. Rowe and Kimbrough found that impotence increased with respect to the type of prostatectomy; for example, they reported 100 per cent incidence of impotence with the radical perineal method. Finkle and Moyers found surprisingly little impotence after prostatectomy, irrespective of the surgical route used.

Neurological disease. Impotence is less of a problem in neurological lesions than is often supposed. Monroe et al. concluded a study of this problem with the statement:

Our series indicates that destruction of the sacral segment of the cord or transection and destruction of the cauda equina and the pelvic parasympathetic plexuses are the only neurologic, anatomic lesions that will prevent the occurrence of erections. Associated with such absence will be an autonomous bladder, an absent anal reflex, and possibly an atonic urethral sphincter. Erections occur in the presence of all other cord injuries, whether partial or transecting, and regardless of the level involved.

Drugs. The agents most likely to be involved are sedatives, tranquilizers, and opiates. The morphine addict frequently has complete impotence. Overdosage with ethyl alcohol often produces impotence during the period of intoxication, although some men report increased sexual ability with a "hangover."

Chronic barbiturate intoxication is likely to result in impotence. Recent reports have indicated that some of the newer psychoactive drugs, the phenothiazines and amphetamines particularly, may produce impotence or ejaculatory abnormalities.

The physician faced with an impotent male patient who is also taking drugs has no choice but to recommend a drug-free trial period of at least 30 days and observe the outcome. Medical judgment must determine whether the condition for which the drugs were used overrides the impotence in importance. Every physician is acquainted with the fact that it is one thing to recommend a drug-free trial period and quite another matter for the patient to follow this recommendation if it involves breaking long standing habit patterns—alcoholism, for example. Further, withdrawal by persons addicted to opiates and barbiturates usually requires hospitalization in the interests of safety.

Psychological factors. The characteristic symptom of psychological impotence is that it is selective in nature—that is, it occurs under one set of circumstances but not under another. Thus, a man may be impotent with his wife but with no one else, impotent with a mistress but not with his wife, impotent with his wife and other women of equal social rank but not with prostitutes, impotent with women but able to obtain erection and achieve orgasm and ejaculation with masturbation, impotent with his wife but potent in sexual dreams, impotent with women but having morning erections, impotent with women but not impotent with other males, impotent with women but not with children or in unusual or deviant circumstances, and so on. There may be, and often are, combinations of these circumstances.

From the diagnostic standpoint, it is of critical importance that the physician obtain a complete sexual history. This in turn requires a good doctor-patient relationship to permit the patient to discuss facts he has held secret and disclosed to no one. It is self-evident that, if a male is impotent in one circumstance but not another, the cause of his selective impotence must be psychological in nature and not due to physical disease or to drugs. In such a patient there is no point in putting him through a series of examinations and tests to discover the cause. It is obvious that no abnormalities will be found to explain the impotence because the patient has adequately demonstrated that his anatomy and physiology of erection are intact.

It is common in psychiatric practice to have a patient referred who is impotent with his wife and who has had a series of tests, cystoscopic examinations, prostatic massages, and a trial on testosterone performed. What he has not elected to tell his previous physicians is that he has been having an affair with another woman, and in this he is perfectly capable. Historical data of this type, which is crucial to an understanding of his problem, usually will not be dis-

closed casually or quickly to the physician. Such a history points to conflict and discord between marital partners, and the impotence is merely a symptom of the underlying personality problems.

In a man who has previously been potent but who is now impotent under a particular set of circumstances, treatment must consist of an investigation into the psychological or emotional stresses involved. This means that the physician must be prepared to spend some time with his patient in running down the factors involved. If the physician does not have the time or does not feel at home in such an area, the patient should be referred to a psychiatrist, if this is feasible. Therapy frequently needs to involve both husband and wife. Because each person and each marriage represent their own unique problems, there is little point in attempting to generalize or to give a number of case histories. There are, however, some types of impotence that are so common that general remarks about them are possible.

Impotence of inexperience. It often occurs that the healthy young male experiences impotence or premature ejaculation at the outset of his heterosexual life. If there is a ready explanation, it is most likely due to a feeling of ineptness, a fear of hurting the girl, feelings of guilt and wrongdoing, an inability to reconcile the loved female with sexual passion, fear of pregnancy, and the like. This phenomenon frequently occurs on the honeymoon in sexually inexperienced young people. As experience is gained, potency is usually gained, and probably few of these situations come to medical attention unless the problem persists for some months.

Impotence only with a wife. There are numerous possible causes of this circumstance, but the most frequent is the development of hostile feelings, either overt or covert, between the partners subsequent to marriage, causing them to withdraw sexually from each other and in other ways as well. Impotence and frigidity under these circumstances can be regarded as symptoms of the disrupted marriage and, in this context, are not primarily sexual problems.

A variation of this type of impotence is that wherein no hostile relationship exists and the wife is much loved. First described in the medical literature by Freud in 1912, complicated psychological forces are involved. In brief, because of emotional factors learned in his childhood, such a man is never able to reconcile a female that he loves with sexual passion. However, he is sexually able with a downgraded female, such as a prostitute, with whom he need form no affectionate relationship. As Freud pointed out: "Where such men love, they have no desire and when they desire they cannot love. They seek out objects (i.e., females) they need not love. As soon as the object fulfills the condition of being degraded, sensual feeling can have free play." After diagnosis, the male with this type of impotence should be referred to a psychiatrist if possible.

Impotence prior to orgasm and ejaculation. Here the penis becomes flaccid after vaginal entrance and terminates coitus before orgasm and ejaculation have been reached. In its simplest form it may occur because a multiparous and lax vagina does not furnish enough frictional grip on the penis to keep the erection in force. Some men object to the use of condoms on the same basis—that they prevent sufficient stimulation to maintain erection.

Fear of being discovered in the act, fear of pregnancy, or a partner who is unresponsive and disinterested may cause erection to vanish after coitus is started. The wife, engaged in intercourse, who makes a casual remark about a household problem, often causes her husband to fail. He is aware that her mind is elsewhere, and his interest vanishes.

Impotence associated with sexual deviation. The predominantly homosexual male may find that he is impotent if he attempts heterosexual coitus, although he is sexually capable in a homosexual relationship. This is because he has little or no physical interest in females; hence, they do not arouse him. Without arousal, there is no erection. For similar reasons, cases of impotence may occur in a man who had been sexually adequate most of the time with casual females with whom he had no close emotional ties or who had been adequate for months or years with a wife. Psychotherapeutic investigation may show this man to have repressed (latent) homosexuality as judged by dream content, strong resistance to discussion of homosexual topics, and the like. He has met increasingly strong unconscious resistance to sexual arousal in a situation that binds him to a heterosexual attachment. Occasionally, one sees the man who for years has maintained both heterosexual and homosexual outlets but who toward middle age becomes impotent in heterosexual but not in homosexual relations. The reverse situation probably occurs, although the author has never seen such a case.

Males who show other sexually deviant behavior patterns—such as transvestitism, bestiality, sadism, masochism, voyeurism, and exhibitionism—are often impotent in the usual heterosexual situation but are orgasmically able in situations that meet the specific criteria of their deviations.

Premature Ejaculation

By definition, premature ejaculation is that condition wherein the male arrives at orgasm and ejaculation before he wishes to do so. Often used to describe the extreme—wherein the male ejaculates immediately after entering the vagina or even before, and the sexual attempt ends in a fiasco—the term also applies to all degrees of prematurity wherein the male is dissatisfied with his performance. The dissatisfaction invariably relates to his having ejaculated and lost his erection before his sexual partner has reached orgasm.

Etiology. There are two divergent points of view as to cause. The psychiatric literature in general and the psychoanalytic literature in particular—Stekel, Abraham, and Bergler, for example—regard premature ejaculation as a form of neurosis. Other authors, with the extreme represented by Kinsey, take quite a different view. In essence, the latter view is that quickness in any human activity represents a superior trait and that premature ejaculation, however inconvenient it may be for the sexual partner, is a sign of superiority. But whether one regards prematurity as a symptom of neurosis or as a superior trait, the fact remains that many men reach orgasm and ejaculation before they wish to do so and hence diagnose themselves as having premature ejaculation. If they consult a physician, it is to enlist his help to delay the response, if this is possible.

Physiology. Arrival at orgasm and ejaculation involves the phenomenon of summation of stimuli, both psychic and tactile. When the threshold of excitability is reached, the reflex fires, and orgasm and ejaculation occur. As in any biological function, one may think in terms of the curve of individual differences; this states that the threshold of excitability is reached in the male population as a result of differing amounts of stimuli but without any implication of pathology or abnormality. The approach to the problem of premature ejaculation can be thought of as involving the following physiological factors: (1) reduction of sensory input, both psychic and tactile, and (2) alteration of the threshold of excitability. If either or both of these factors can be changed, it follows that the time of arrival at orgasm and ejaculation can be changed also.

Treatment

Inhibition of psychic component. In clinical practice, one hears men describe their own methods of delaying response. Those that involve the psychic component are: (1) occupying the mind with non-sexual fantasy (this can be almost anything—reliving a hunting trip or golf game, doing the multiplication table, and so on); (2) tightening the anal sphincter as much as possible and concentrating on keeping it tight (recommended by Kinsey); (3) bodily maneuvers, such as pinching the skin of an arm, lightly biting the cheek or tongue; and (4) judicious use of alcohol, a cerebral depressant.

Reduction of tactile component. This involves reduction either in the amount of intensity of vaginal friction or in the excitability of the receptor end organs in the glans penis. As to the latter, Aycock reported that the use of an anesthetic ointment rubbed into the glans has been tried with indifferent results. Although some men object to the use of condoms because the alteration of tactile stimuli prevents them from keeping the erection in force, other men find condoms to be a solution to their problem of premature ejaculation. The amount of vaginal friction may

be reduced materially by limiting the frequency of thrusts or the extent of penis travel within the vagina. If the penis is deeply inserted in the vagina and penis travel is limited to short strokes, of about an inch performed slowly, summation of tactile stimuli is reduced, and the threshold is reached more slowly. Some men report an ability to postpone orgasm and ejaculation indefinitely by this method and must increase the frequency and length of thrusts to reach it. It is a useful technique with the sexual partner capable of multiple orgasms.

Alteration of threshold of excitability. Semans reported a method that in his experience, was highly successful in treating prematurity. In brief, the male or his wife stimulates the erect penis in a masturbatory fashion until the premonitory sensations of impending orgasm and ejaculation are first felt. The penile stimulation is stopped abruptly at this point, and orgasm and ejaculation do not occur. Sexual excitement and possibly the erection subside over the course of the ensuing minutes. The stimulation is then started again, and, as before, it is stopped at the first sensations of impending orgasm. As Semans reported, "By repeating the procedure, the response of ejaculation becomes no longer premature; that is, it can finally be delayed indefinitely until female response has begun or is complete." This technique appears to be one that trains the threshold of excitability to be more tolerant of the summing stimuli. Once the desired coital pattern has been established, it appears to remain a stable one. The technique recently reported by Masters and Johnson appears to follow similar principles.

Psychotherapeutic management. The psychiatric and psychoanalytic literature report favorable results in prematurity following long term therapy that investigates conscious and unconscious attitudes toward sexuality stemming from childhood training and experience. It constitutes a therapeutic technique that may well bring success in patients with neurotic attitudes about sexuality, toward the female, and so on. The writer must admit that most of his psychotherapeutic efforts have failed to change the premature response pattern. Obviously, this does not mean that psychotherapeutic management in other hands may not achieve better results.

Suggested Cross References

For a further discussion of the sexual disturbances that underlie some cases of impotence, see Sections 26.3 and 26.4 on homosexuality and other sexual deviations, respectively. Lief and Reed's section (Section 5.7) in Area B, on the basic behavioral sciences, contains a discussion of normal sexuality. For a review of corresponding psychophysiological genitourinary disorders in women, see the next section in this chapter. Work's section in Area H (Section 41.6) contains a discussion of sexual disturbances in children.

30.8 OBSTETRICAL AND GYNECOLOGICAL DISORDERS

HENRIETTE R. KLEIN, M.D.

Current theoretical formulations and research studies of genitourinary and obstetrical problems tend to combine the advantages of both physiological and psychological orientations and, concomitantly, to stress the interaction of psychic and somatic factors. On still another level of investigation, workers have begun to underscore, to an increasing degree, the intimate relationship among specific visceral organs, genetic dispositions, pain thresholds and other somatic factors, and gynecological dysfunction. The ensuing discussion will be restricted to the psychogenic components of such dysfunction.

Menstrual Disturbances

Few somatic phenomena are so well suited to serve as a focus for discussion of psychophysiological

correlations as menstrual disorders. Such disturbances may take various forms and produce symptoms which range in severity from mild discomfort to intense pain. However, psychological factors are present in almost all forms of menstrual disorders. Current theoretical formulations concerning the psychological aspects of female sexual function are reviewed briefly below. This discussion will then proceed to consideration of the application of these principles to three common forms of menstrual disturbance—dysmenorrhea, amenorrhea, and premenstrual tension.

Psychological determinants. According to classical psychoanalytic theory, in a broad sense, the psychological problems underlying a variety of menstrual disorders can be attributed to disturbances in the patient's feminine identification. More specifically, Freud's theory of psychosexual development provided the springboard for subsequent investigations of adult female sexual function.

Oral stage. Benedek and others consider the oral stage of development a crucial determinant of future sexual function. These workers have stressed, in particular, the importance of the principal interactional unit of the infant-mother relationship, as circumscribed by the feeding situation. The ability of the mother to gratify the infant's oral needs will, in turn, affect the infant's general feeling of well-being and the course of its primary identification with the mother. If, on the other hand, the feeding situation is a frustrating emotional experience, ensuing mother identifications will be tinged with fear and hostility and ultimately result in the infant's reluctance to identify with the mother. Furthermore, when a barrier to feminine identification has been established during the early part of life, it becomes difficult to achieve such identification at succeeding stages of the development.

Deutsch and others have emphasized the unconscious penis-breast association as a crucial determinant of later sexual functioning. Briefly, the anxiety provoked by the trauma and frustration associated with the breast (nursing) will subsequently be attached to the penis and inhibit sexual pleasure.

Anal stage. Freudian theory further states that during the period of bowel and bladder training (anal stage) the infant's basic attitudes toward his own body functions are established. Thus, too stringent or premature an emphasis on sphincter control may make for considerable fear, hostility, or guilt toward bodily functioning in general, and toward associated anal-urethral functioning in particular. Later, unconscious associations to menstrual, urinary, and fecal discharge may cause a reactivation of the intense fear, hostility, and guilt established during earlier developmental stages, particularly of the power struggle between child and parental figure involved in bowel and bladder control.

Genital phase. During this stage in development, the female child becomes increasingly aware of the

biological differences between the sexes. Concurrently, she becomes aware of the fact that she possesses an organ, the clitoris, which can be pleurably stimulated, while boys possess an organ, the penis, which she lacks. The sexual self-stimulation and attendant guilt associated with the former discovery, and the penis envy and fear of castration associated with the latter discovery, become interwoven with her sexual and love strivings. And, inevitably, her feelings of self-blame or responsibility for absence of penis, or being maimed, are associated with sexual self-stimulation and related fantasies. These developments may, in turn, give rise to consequent feelings of resentment toward males because of their "superior" biological accoutrement (penis), and because of their dominant cultural role—a factor emphasized by Horney, Thompson, and others. In any event, the manner in which such early conflicts are handled will either foster or hamper feminine identification and genital functioning; as such, they constitute a crucial determinant of mature female sexual functioning.

Puberty. Menarche may occur at any time from the beginning of puberty on. It is no longer equated with sexual maturity, which occurs at a later date; however, its emergence makes conspicuous or exhibits, as it were, the girl's femininity. And, with the onset of menstruation, there is a reactivation of prepubescent anxiety which has its origins in more primitive sexual drives and attendant guilt surrounding these drives. Particularly common are self-consciousness, self-hate, resentment of the feminine role, castration fears, and masturbatory guilt. According to psychoanalytic theory, the unconscious identification of menstrual discharge with mutilation further interferes with the girl's psychological acceptance of this physiological phenomenon.

Dysmenorrhea

Definition. Dysmenorrhea, which refers to a variety of painful menstruation, is perhaps the most prevalent of the menstrual disorders. However, it is generally believed that this type of dysfunction has become less common, due to cultural changes. Among these, increased freedom in expression of sexual needs and behavior has lessened the psychological burden formerly imposed on the woman.

Clinical features. The four major symptoms of dysmenorrhea comprise severe and protracted pain, with concurrent discharge of blood clots; pain from hyperemia and distention, which occurs directly prior to menstruation, and subsides rather quickly after the onset of menstrual flow; membranous dysmenorrhea; and, finally, menstrual colic, accompanied by abdominal distress, nausea and vomiting, migraine, tachycardia, anxiety attacks of variable depth and duration, and fainting spells.

Physiological mechanisms. The physiological mechanisms operative in dysmenorrhea include a wide range of somatic phenomena. Foremost among these

mechanisms, according to Haman, is the lowered pain threshold found in dysmenorrheic women, which makes them more sensitive to uterine contractions, which are not usually perceived by other women. Research investigations have also implicated associated physiological mechanisms, including ischemia of the myometrium, vasoconstriction, tissue fragility, and fibrinolysis of menstrual debris.

Psychological determinants. Basic etiological considerations concerning the psychological determinants of dysmenorrhea derive from the woman's underlying image of herself and her sexuality. As mentioned earlier, menstruation is considered the badge of femininity. And menstrual onset, its earliest and foremost symbol, may serve to precipitate, or reactivate, many related fears. Menstrual flow may be associated, for example, with punishment for previous sexual wrongdoings, such as prepubescent sexual self-stimulation, unacceptable sexual fantasies, or feelings of hostility and rivalry with the mother for the love of the father. Furthermore, the repressed fears and guilt activated by menstruation may be expressed through visceral outlets. Simmel, among others, believes that the organ chosen is not fortuitous; rather, it is predicated by the nature of the underlying emotional conflict.

Still another etiological factor, emphasized by Benedek, derives from the woman's basic reluctance to accept her feminine role, as symbolized by the menstrual experience. Earlier identification conflicts, stemming from repressed hostility toward the mother and an underlying jealousy and envy of masculine dominance, are brought to the fore by menstrual onset. Thompson's detailed account of the cultural factors involved, particularly the resentment of masculine dominance, elaborates on this possible etiological aspect.

Finally, underlying attitudes toward the body orifices and the eliminative functions may be reactivated by menstrual onset. If a strong sense of repressed guilt and anxiety has been established during the early stages of development, centering around toilet training, all eliminative contents and orifices may be perceived in later life as dirty and shameful. The equation of expulsion with hostility and its attendant guilt may well be reactivated during menstruation, as may be the assumption of being mutilated. Consequently, the apprehension, discomfort, and occasional pain which may accompany menstruation may be magnified by psychological conflicts which have been reactivated by the menstrual process itself. And, concomitantly, guilt feelings may be expressed through somatic symptoms revolving around menstrual activity.

Amenorrhea

Definition. The various types of psychogenic amenorrhea are differentiated on the basis of the degree of dysfunction, as well as the extent and nature of the

symptomatology involved. In general, amenorrhea refers to the absence of menstruation. Under this broad rubric, the more common categories are oligomenorrhea, which refers to sparse menstrual flow for prolonged intervals, ranging from several weeks to several months, and even years; and pseudocyesis, which refers to false pregnancy.

Clinical features. As mentioned above, the primary symptom of oligomenorrhea is scanty menstruation. Pseudocyesis is accompanied by the classical symptoms of pregnancy, which, in addition to the complete cessation of menstruation, include nausea, enlargement and pigmentation of the breasts, abdominal distention, and even simulated labor pains. Only well documented evidence of the absence of pregnancy or tumor permits this diagnosis. Clinically, it is found chiefly in women of hysterical or schizotypal organization.

Physiological mechanisms. In amenorrhea, the chief physiological mechanisms involve the derangement of characteristic hormonal patterns, as a result of the suppression of hypothalamic influences on the anterior pituitary gland. In the absence of luteinizing hormone, the ovarian follicle does not produce ovulation. There is ample evidence, however, that the structure of the endocrine system makes it vulnerable to emotional influences. Research studies have also demonstrated that the absence of the hypothalamic stimulus can be traced to emotional factors. Conversely, when emotional stress decreases, estrogen production and cyclic activity have been found to return to normal. Recent research has thrown new light on the interrelationship of emotional, hypothalamic, and ovarian components.

Psychological determinants. Etiological formulations permit a clear distinction between the phenomena of oligomenorrhea and pseudocyesis. Foremost among the psychogenic factors in oligomenorrhea is the repression of the ovarian cycle. Such a reaction may occur in response to a variety of stressful experiences, such as extreme physical danger or the psychic stress precipitated by the loss of a loved object. According to some workers, suppression of ovulation characteristically occurs as a concomitant of the fear and unconscious denial of gender and sexuality.

The variety of conflicts concerning feminine identification, mentioned above in connection with dysmenorrhea, are believed to play an integral role here too. It may also be speculated that the repression of menstruation represents an attempt to avoid activation of earlier developmental conflicts, particularly those associated with the anal stage of development.

In pseudocyesis, the objective signs of pregnancy in the absence of pregnancy derive from the pathological wish for or fear of pregnancy. Thus, this symptom may serve as an expression of conflicting attitudes regarding childbearing and related female sexual functions. Benedek and others have also emphasized the unconscious hostility of pseudocyclic

women toward children, and they hypothesized that resulting guilt feelings give rise to this symptomatic expression which represents an attempt to undo these hostile impulses. A deeply rooted fear of the dangers of childbearing, representing unconscious self-destructive impulses, presents another possible explanation for this phenomenon.

On the other hand, various authors have pointed out the significance of the intense desire for pregnancy which produces this clinical picture, which is sometimes defined as conversion hysteria. Pregnancy symbolizes a fully feminine achievement, and its alleged existence may serve to undo the guilt resulting from contradictory sexual tendencies. The fantasied pregnancy can serve, not only as an instrument in the woman's fight for sexual identity, but also as a means of competing with her mother and of satisfying unconscious early strivings. It may indicate a desire to hold the husband, and, as such, be perceived as a reaffirmation of the woman's youth, potency, and desirability. Thus, the wish for pregnancy, which is pathological in its intensity, may represent the patient's attempt to gain fulfillment of her intense and unfulfilled dependency needs.

In summary, then, this clinical phenomenon may express feelings ranging from an intense fear of pregnancy to a pathological wish for it. In either case, the symptom is the outcome of magical thinking, aimed at resolving the forces which underlie these unconscious fears and wishes. As such, pseudocyesis is found in severely disturbed women. At the same time, because the expression of unconscious wishes and fears is so dramatic, it highlights effectively the role of unconscious psychological factors in producing somatic changes.

Treatment. With specific reference to oligomenorrhea, provided the patient does not manifest severe underlying psychopathology, a supportive and reeducative program regarding menstrual processes may facilitate a return of the normal cycle. Similarly, removing the major external and endogenous conditions related to emotional stress may serve to alleviate the somatic expression of such stress. The crucial diagnostic question is whether the amenorrheal condition is the comparatively benign expression of a more deeply rooted, malignant psychopathology, in which the menstrual cycle has a dramatic symbolic significance. Obviously, in such cases, more intensive psychotherapy is imperative.

In general, however, the treatment of the clinical entities of oligomenorrhea and pseudocyesis should encompass the knowledge that these somatic manifestations are part of a larger constellation of maladaptation. Psychotherapeutic plans, therefore, should not focus upon the presenting symptom, but on the patient's current life situation, specifically, her underlying fears, hostilities, and guilt feelings. For the most

part, the course and strategy of treatment of these clinical disorders follow the individual application of the standard therapeutic techniques for psychosomatic disorders discussed below.

Premenstrual tension

Definition. Premenstrual tension can be distinguished from more general premenstrual discomfort on the basis of the extent of the patient's disability and, most importantly, the strength of its relationships to underlying fears and distortions.

Clinical features. The physiological symptoms usually include edema of various tissues, engorgement of the breasts, and bloating and discomfort in the abdominal region. Accompanying symptoms may also include nausea, vomiting, and diarrhea.

The psychological manifestations which accompany these cyclic physiological complaints include irritability, impatience, anxiety, fatigue, depression, or alternating moods, such as fits of weeping and euphoria. In addition, bouts of regressive or compulsive behavior in the form of preoccupation with bodily cleanliness, housecleaning, and the like have been reported.

The above symptoms are highly prevalent and are said to be present in 40 per cent of all women who suffer from menstrual disturbances.

Psychophysiological mechanisms. The interrelationship of physiological and psychological factors and, in fact, the correlation of cyclical hormonal activity and consequent mood changes have been demonstrated in research studies. Briefly, the hormonal imbalance responsible for fluid changes in tissues directly preceding menstrual onset puts further stress on the integrating and controlling functions of the ego. If the adaptation is already somewhat tenuous, the added burden of menstruation may disturb fragile controls.

In summary, while an organic predisposition seems to be present in some forms of menstrual disturbance, such as dysmenorrhea and premenstrual tension, in other cases of menstrual disorder, the symbolic significance of menses is a crucial factor. And, in such patients, the somatic symptoms can be viewed as an expression rather than the cause of the patient's general distress.

Both physiological and psychological treatment methods are used in the management of menstrual disorders. The treatment approach varies with the individual case. Some cases of premenstrual tension respond to hormone therapy, others to psychotropic drugs; however, the treatment of choice for the majority of patients is psychotherapy. Finally, as mentioned earlier, the psychotherapeutic treatment of this patient population should focus on the total life situation in the context of previously established attitudes, rather than specific, isolated symptoms.

Pregnancy and Childbirth

Pregnancy

Psychodynamics. In the psychologically mature woman, the wish to be pregnant is viewed as a primary pleasure, the woman deriving pride and satisfaction in the pattern of reproduction unique to the female, and in the uniqueness of the activity. According to Helene Deutsch, the reproductive process is "the direct fulfillment of the deepest and most powerful wish of the woman" and in the healthy woman, pregnancy is an expression of her sense of fullness and self-realization, rather than her doubts and frustrations.

Pregnancy may also have a variety of psychopathological meanings, however. For one, since reproduction satisfies the belief in immortality, it supports early omnipotent feelings. Other motivating forces may also accompany, or gain preeminence over, the healthy drive for motherhood. These may include, for example, the desire to revive a shaky marriage, to diminish self-doubts concerning femininity, or to assuage deep aggressive drives. Pregnancy may provide enormous regressive and substitutive gratifications, the powerful motivating forces being the need to compensate for a sense of loss (penis), or a restitutive or reparative motive (castration fear and guilt). Pregnancy may represent strong competitive drives toward mother or an older sister, or excessive competition with the male. And, finally, pregnancy may express the female's doubts as to her adequacy or her right to be loved for herself.

Freud hypothesized that the frustration caused by the lack of a penis was the central motivating factor in female psychosexual development, and he concluded that the woman's wish for a child was motivated by her wish to retain the penis, more specifically, her father's penis, symbolically. According to this concept, a male child represents the fulfillment of the originally repressed wish. Insofar as the concept of penis envy is related to infantile fantasy, it may be among the significant fantasies which are revived during pregnancy.

Clinical features. There is no gainsaying the fact that pregnancy, even in the emotionally mature woman, may tax her physical reserves. But many of the somatic symptoms observed during pregnancy may express varying degrees of emotional dysfunction. To begin with, life situations may present real obstacles and barriers to what might, under other circumstances, be considered an ideal attitude toward childbearing. A faltering marriage, an attempt to hang on to one's spouse, economic considerations related to the present size of the family or to the timing of the pregnancy, professional obligations, including the traditional conflict of the career woman who does not want to be tied down—all these may be expressed through any number of somatic symptoms.

The crux of the woman's problem often lies in her fears concerning some symbolic aspect of childbearing. The fact remains, however, that while pregnancy may accentuate existing severe psychopathology, faulty emotional attitudes expressed in pregnancy are not intrinsic or inherent to the childbearing process, but are mobilized by it.

Psychophysiological mechanisms. Benedek's attempts to correlate hormones and metabolism with the sex drive, including the desire to be pregnant, are relevant in this connection. Since hormones stimulate specific emotional responses, and psychological factors, in turn, influence hormonal regulation, there is a continuous interaction. The preovulatory period, under the influence of estrogens, is marked by increased sexual desire, which is maximal during ovulation. After ovulation, the progestational influence is at its peak, and this encourages the woman's passive-receptive needs—the desire to be loved and protected.

The development of the female progresses from infantile narcissism, or concentrated pleasure in self, to the point where, to quote Deutsch, the ego has "the capacity for tenderness, altruism, and a specifically colored activity." The initial dependency, as seen in the symbiosis with the mother, and the ensuing magical wish for omnipotence and possession are linked first to the digestive tract. And, in fact, the early alimentary pattern exerts a powerful force (which is incorporated as a crucial component into the later wish for a child) as an expression of dependency. The female child attempts to gratify these dependency needs by ensuring possession, first of mother, and later of the father, through a variety of coercive moves. The father becomes more significant with the female's increased awareness of biological differences between the sexes, and she fantasies that he will replace the organ she has been deprived of. During puberty, there is a strengthening of feminine identification and identification with the mother, which will be strongly influenced by previous psychological events involving identity and body image.

These attitudes may be reinforced by pregnancy and expressed somatically. The endocrinological and metabolic demands of pregnancy usually give rise to symptoms associated with psychological factors, i.e., nausea, fatigue, headaches, or vomiting. Additional symptoms may be accentuated as well, including anorexia, vertigo, or even severe metabolic disturbances. Oral and hostile rage in response to unfulfilled omnipotent infantile needs may be reactivated during childbearing, so that the woman feels so self-destructive and unworthy that the fetus represents a hated or feared person. In fact, hostile and destructive attitudes toward the unborn child, self, and others, and feelings of inadequacy are not uncommon. And all these attitudes may be channeled through the physiological symptoms of pregnancy or expressed through fears which appear to be very realistic. Such symptoms may also provide secondary gains: they

may permit the woman to avoid household chores and sexual activities and, above all, permit her to indulge her dependency needs.

Unfavorable life situations, such as a too recent pregnancy, may color the woman's acceptance of pregnancy, or her capacity to cope with it. But the reverse may also be true: when the woman's oral-receptive needs are met, she may function better during the period of pregnancy than she did before and take pride in an uneventful and complaint-free childbirth.

Treatment. Fears surrounding pregnancy or childbirth, which are probably found in every woman to some degree, may center on the unborn child or the pregnant woman herself. The focus is interchangeable, mother and fetus being mutually substitutive. But it is usually easier for the woman to talk spontaneously about her fears concerning the unborn child than to discuss her own fears.

Whatever her psychological and physiological status, the prenatal period should include regular visits to the physician to provide continuing observation of the patient. Such visits permit an opportunity for examining problems or disturbing thoughts as they arise. Early involvement of the father and other family members with the unborn child should also be stressed.

Childbirth

Labor and delivery. Current interest in the obstetrician's management of the pregnant woman, following the work of Grantley Read and subsequent investigators who described the fear-tension-pain syndrome in labor, is aimed at diminishing the fear of delivery and reducing the tension-pain response. Similarly, increased understanding of the psychodynamic processes involved in labor have resulted in additional constructive modifications, primarily the use of anesthesia.

The interaction of physiological and psychological factors occurring at any time during pregnancy may be carried over or released during the process of labor, or immediately thereafter. For example, the woman may not be ready to give up her sense of unity with the child, or she may experience a feeling of emptiness or feel guilty over her insufficient love for the newborn. Such feelings may be expressed in mood changes, ranging from mild moodiness to severe depression, or malignant erratic behavior during the lactation process.

Lactation. There is ample proof that lactation can be influenced by emotions. However, more sober investigators have wisely emphasized the fact that the wish to nurse is not the equivalent of the ability to nurse, or vice versa. Depending upon crucial factors in the woman's early development, differences in degree of "maternal feeling" are inevitable. This may not be crucial, unless the woman attempts to hold herself to an ideal of what motherhood entails. In that event,

guilt about her inability to nurse the child or her lack of interest in doing so may become a focal point for her inner distress and be expressed through somatic dysfunction.

Postpartum period. Again, in the period following delivery, the psychodynamic factors which determine the woman's over-all sexual adaptation may be taxed to the point where they seek expression in somatic symptoms. These may take the form of lack of appetite or self-interest, absence of sexual interest, chronic or persistent fatigue, or mood changes. The last are certainly not uncommon, and sometimes more severe reactions are seen in the postpartum period. Some investigators have stressed the fact that emotional decompensation seen in the postpartum period expresses dysfunction and maladaptation which may have existed prior to impregnation. In some instances this dysfunction and maladaptation may have been responsible for the pregnancy, rather than the result of childbirth. The woman may be more vulnerable psychologically during this period: the hormones are facilitating agents which influence the thresholds of response patterns, and ovarian function is not established with regularity until after lactation is complete. Nevertheless, it is generally agreed that when a psychosis manifests itself in the postpartum period, its form has been predetermined by the woman's previous emotional organization. Some have viewed severe postpartum dysfunction as release phenomena, which facilitate the overt expression of underlying pathology, the clinical picture usually being that of depression or schizophrenia.

The clinical management of postpartum psychosis is considered in detail elsewhere in this volume. In brief, physiological treatment techniques, in the form of hormone therapy and psychoactive medication, as well as psychotherapy, would appear to constitute an appropriate treatment approach to this syndrome.

Sexual Disturbances

In the motivation for sexual intercourse, the desire for orgasmic gratification generally takes precedence over the desire to reproduce. Rado described coitus as providing the human organism with a source for overwhelming pleasurable accumulation and discharge of its superabundant emotional tensions. This formulation supports Freud's hypothesis that sexual frustration plays a large part in the etiology of certain behavior disorders; it also explains why any interference with the achievement of such pleasure and the discharge of these emotional tensions may precipitate emotional disturbances with their multiplicity of somatic expressions.

Physiological determinants. A few general remarks which are applicable, to some degree, to all forms of female sexual dysfunction may serve as an appropriate preamble to this discussion of specific female sexual disturbances. To begin with, the study of physiological, as opposed to psychological, factors

has been especially neglected in this area. Yet, the role of higher cortical centers in either facilitating or inhibiting spinal centers which respond with a reflex to mechanical stimulation is particularly crucial. This cortical stimulation (or inhibition) is, in turn, a product of the total psychodynamics of the patient, including experiences at different levels of consciousness. It is the cortical activity which determines the response described as pleasurable sensations. Moreover, as Marmor has pointed out, given the same amount of clitoral stimulation, the cortical centers determine both the intensity and the duration of orgasm.

Secondly, it should also be pointed out, in this connection, that the phenomenon of orgasm in the female is by no means synonymous with pleasurable sensations, although one facilitates the other. In fact, according to Dickinson and Beam, only two out of every five women in our society experience orgasm regularly. However, the woman may derive certain satisfactions from sexual intercourse, and experience pleasurable sensations, even when she does not achieve orgasm. Yet, while some women who are too inhibited to have an orgasmic response are able to enjoy sex nevertheless, more frequently, it is experienced as a sign of inadequacy and as such becomes another factor leading to her distress. Thus, patients in this category may be divided into two groups: the first group "enjoys sex, but cannot have an orgasm"; the second "cannot have an orgasm, so they cannot enjoy sex." Furthermore, the patient's specific attitude in this respect is frequently believed to have important implications in terms of etiology, treatment strategy, and prognosis.

The third related point for general discussion refers to the fact that, for many years, it was assumed that the female's response to vaginal, rather than clitoral, stimulation was an important criterion of psychosexual health. And, as such, this orientation was fundamental to the therapeutic approach to female sexual disturbance. However, the hypothesis that clitoral sensitivity must eventually give way to vaginal sensitivity in the course of "normal" psychosexual development is no longer considered tenable in the light of recent data. Rather, it is generally agreed that clitoral excitation in the process of sexual intercourse is an essential factor in the stimulation leading to orgasm. Although there are secondary erogenous zones, such as lips, breasts, and buttocks, in women, the chief erogenous zone is localized in the glans clitoris. Thus, Masters and Johnson have shown that failure to achieve orgasm during intercourse is often related to inadequate clitoral stimulation.

Frigidity

Definition. The term frigidity, or sexual anesthesia, is a term which is used to designate a variety of sexual disorders relating to the inhibition of female sexual response, ranging from "unsatisfactory" orgasm (but otherwise vigorous sexual response) to

complete lack of response to sexual stimulation. In all of its manifestations, frigidity represents the form of psychogenic sexual dysfunction which is encountered most frequently in clinical practice.

Psychodynamics. Bypassing, for the moment, the infrequent physiological causes of nonorgastic response, such as the effect of the ovarian cycle, the numerous psychological factors associated with this disorder in women are variously ascribed to the fear of impregnation, fear of rejection by the sexual partner, envy or hostility toward the male, and fear and/or guilt regarding penetration and impropriety of the sex act. Sex is viewed as an act of violence and there is fear of mutilation. Consequently, any sexual activity, coitus in particular, is perceived as a threat.

Frigidity may also be used as a weapon against the male. To the woman who feels inferior, and therefore hostile, to the male because of anatomical differences and social roles, or because of her dependency upon the male, with its concomitant frustration, sexual nonparticipation may be a bid for independence. Frigidity may also be a defense against earlier unacceptable impulses, such as competitiveness with the mother or forbidden sexual fantasies. The inability to assume a female orientation, because of a preoccupation with competition or domination, may lead to a diminished capacity for sexual pleasure. Again, the release phenomenon of orgasm may be equated with loss of control and with concomitant aggressive, destructive, or violent behavior. Fear of these aggressive or destructive impulses leads to damaged self-esteem and the expectation of retaliatory behavior from the male, and it contributes to sexual inhibition which is expressed in nonorgastic response.

Dyspareunia and vaginismus

Definition. Although dyspareunia, which refers to painful or difficult sexual intercourse, and vaginismus, which refers to an involuntary spasm of the vaginal muscles, are differentiated from frigidity, the underlying psychological factors operate from the same base line of fear, hostility, and guilt, and they lead to the same consequences, i.e., sexual avoidance, sexual displeasure or aversion, and varying degrees of pain or discomfort. On the other hand, dyspareunia and vaginismus are less prevalent than frigidity and generally indicate the presence of more severe pathology.

Psychophysiological mechanisms. Kroger and Freed have pointed out that the terms "dyspareunia" and "vaginismus" are used interchangeably in the gynecological literature, although attempts have been made in both cases to differentiate demonstrable pathology from psychic factors. This discussion is limited to consideration of these symptoms as a somatic expression of psychological maladaptation and a defense against sexual intercourse. Thus, in vaginismus, the involuntary muscle spasm which expels the penis and renders coitus impossible may express

the force with which the woman desires to prevent entrance into her body, her reproachment of the act itself. Her perception of the male sexual organ as a dangerous weapon which will damage her by penetration leads the female to lose her capacity for sensation. Whatever the underlying factors in her inability to participate actively and derive pleasure from sexual intercourse, her concern with this failure and her fear of it will then reinforce her distress and her fears that she is unfeminine, or homosexual. Similarly, in dyspareunia, the psychogenic fear of anticipated pain makes intercourse unbearable or unpleasant.

Treatment. Any therapeutic procedure must, of course, include removal of organic factors, when present. However, the psychogenic components of these disorders are more readily apparent. The more common and frequent psychological determinant of unpleasant and painful coition refer to the woman's relationship with the partner, realistically and symbolically. Although these may be based upon her deep-seated problems, the difficulties in the relationship per se and the problems inherent in the partner must be taken into account as well. Indeed, all of these factors must be assessed and utilized in outlining an effective therapeutic program.

Ideally, the therapeutic plan will include education and reeducation of both partners to enable increased awareness of sexual technique and relationship pitfalls, as well as increased understanding of the part each partner plays in the problem of the other, even though maladaptation in the sexual area may be rooted deep in the personality structure. Once it has been established, when variations occur in the usual orgasm pattern, they may then be related to other disturbances, such as illness, including depression; increased tension of one partner; or increased tension in the relationship.

Social and internal pressures which characterize female development in our society; excessive masturbation with independent orgasm and subsequent dependency on secondary stimulation to the exclusion of the sexual act itself; ignorance of sexual techniques; moral, religious, and parental prohibitions; fear of dependency, on the one hand, and the expression of aggressive impulses, on the other; and excessive guilt and fear of coitus all impinge on the freedom of the female to develop her capacity for sexual pleasure and her ability to perceive it as a source of satisfaction. Other cultural demands, such as the emphasis on virginity as a prerequisite for marriage, further complicate the picture. Nevertheless, despite such impediments, psychotherapy may be remarkably effective in such cases.

Fertility problems. Through the comparative study of animals, Beach and other investigators have clarified the part psychodynamic integration plays in sexual behavior. With the development of the brain in the evolution of vertebrates, mating behavior has

become more complex. The sexual pattern of the individual woman is shaped by highly complex social forces which are in constant interaction with her biological equipment. Although, as mentioned earlier, coition is dominated by a desire for orgasmic pleasure and is independent of reproductive intent, which may or may not be present at a given time, deeper attitudes toward coition, menarche, childbearing, and menopause are intertwined.

Psychophysiological mechanisms. Though the physiological mechanisms of involuntary sterility are not yet completely understood, investigators repeatedly stress the crucial interplay between psychogenic and physiological factors in the sensitivity of the endocrine system of the reproductive apparatus.

Rubin and others have called attention to the importance of tubal spasm in sterility, where the constriction of the smooth muscle at the uterotubal junction prevents ovum and sperm from making contact in the tube. Since the smooth muscle of the female genital tract is particularly susceptible to hysterical spasms arising from emotional stress, Stallworthy considers this spasm to be a manifestation of the autonomic disharmony operating in the patient.

The frequent occurrence of conception after seemingly sterile couples have adopted a child is also considered by some to reaffirm this interplay of psychic and physiological disturbances in low fertility and to underscore the role of unconscious emotional factors. Hanson and Rock, on the other hand, have advanced another interpretation of this phenomenon. They suggested that the possibility of improved relations between husband and wife, relief from anxiety over childbearing, diminished conflict about motherhood and the general increased sense of well-being—all of which may be consequences of the adoption—help to facilitate conception. However, these conclusions were based on data garnered from questionnaires that did not attempt to explore unconscious factors, which might have been crucial in the previous failure to become pregnant. Other investigators, too, have pointed out that in some instances the improvement in the psychological well-being of the woman and in the marital relationship, in general, may have occurred prior to the adoption and have suggested that data concerning postadoption impregnation needs careful review.

Various authors have expressed a preference for terms, such as limited fecundity, and subfertility, as opposed to sterility. This is not merely a question of semantics, since a physiological predisposition does appear to exist. A woman whose somatic constitution renders her highly fertile, given the very same fears, hostilities, and hysterical traits, will still conceive with relative ease and express her fears, anger, and guilt in other ways. On the other hand, when a woman's physiological predisposition renders her subfertile and she is, in addition, marginally adapted psychologically for reproduction, emotional factors

may interfere sufficiently for sterility to result. However, this does not mean that psychic factors are the sole determinants of sterility.

Psychological determinants. Obviously, the fear of impregnation may be a crucial factor in the inability to conceive. Such fears might include an unwillingness to take on changes in the current life situation or to have less freedom for other activities, increased commitment to a marriage with which the woman is dissatisfied, or fears of childbirth. Many of these fears are experienced at a conscious level.

Unconscious fears may be more serious, including the woman's fear of surrendering the father-daughter relationship she has enjoyed with her husband and having to compete with a child for his affection, and hostility toward the male, both of which may be expressed by a stubborn "refusal" to conceive. The psychodynamic factors operating in the unconscious rejection of pregnancy by women who seem to desire it approximates the general concept of maladaptation in the sexual area as delineated above. In certain women, the woman's need to repudiate the feminine role may be expressed in the form of amenorrhea; in others, the disturbed emotional patterns are reflected in the inability to become pregnant.

Treatment. In addition to the need for a careful biological survey, treatment must be based on careful evaluation of the total relationship between husband and wife, of the nature and origins of the woman's feelings of frustration, and of the accompanying feelings of anger or incompatibility. Because of the sensitivity to all components in the sexual cycle and sexual behavior, intrusive attitudes may well trigger motor discharge of tension through the uterotubal spasm described above.

Increased tension and anxiety may result, as well, from the woman's failure to conceive initially or after repeated attempts, particularly when there is excessive focus on this problem. Her fear of being childless, empty, and unfulfilled may be equated with the male's dread of impotence. Such a self-image may augment emotional duress in subsequent coital attempts and make impregnation even more unlikely. In such instances, reduction of tension by means of relatively simple measures, such as reassuring the woman on this score, prescribing sedation, or even the seemingly stereotyped suggestion of a vacation may yield favorable results.

Since conscious or unconscious avoidance of exposure to impregnation during ovulation results in infertility, the importance of a careful and detailed history before a diagnosis of sterility is made should be underscored. Detailed accounts of frequency and time of intercourse, as well as the emotional disposition of the woman during and directly after intercourse are essential in this connection.

Careful scrutiny of the woman's capacity for sexual pleasure is also indicated; there are frequent reports of cases where alleged sterility and frigidity

are alleviated concurrently. Investigation of the husband's attitude toward the prospect of becoming a father and toward his wife's supposed inability to conceive, as well as his own attitudes concerning marriage or family foundation, provides data which facilitate further understanding. Inevitably, the husband's attitude contributes to his wife's tension in general and during intercourse in particular; and by so doing he may have intensified her basic problem of subfertility.

Menopause

Turning briefly to the somatopsychic symptoms related to the menopause, typically, the woman's attitude toward this gradual decline in her reproductive capacity draws on many early fears. These are now reinforced by her concern that she will be less attractive to her spouse, or as a woman; that she will be incapable of sexual participation or sensual pleasure (together with shame and guilt because of her persistent sexual stirrings); that the menopause is a period of disturbing changes and symptoms; that she will be abandoned and become old and purposeless. These attitudes may be expressed in irritability, hypersensitivity, excessive complaints, or multiple somatic symptoms. Reeducation and redistribution of general understanding of the illusory threat of menopause are helpful psychotherapeutic tools, in addition to physiological procedures, such as hormonal replacement therapy and administration of psychoactive drugs.

Abortion

"Habitual" abortion. Spontaneous abortion occurs in 10 per cent of all pregnancies. "Habitual abortion"—that is, at least two consecutive abortions—may be attributed to physiological, as well as psychological factors. Nevertheless, despite the fact that it is certainly not exclusively psychogenic in etiology, the emotional consequences of abortion are usually serious enough to demand careful medical attention. Such an experience may well be the first traumatic psychological experience in the marriage. In that event, the physician may assuage the woman's uneasiness, self-reproach, and guilt, to some extent, by emphasizing the facts that spontaneous abortion is frequently an indication that an abnormal sperm has fertilized the egg and that abortion is highly preferable to the continuation of pregnancy which would result in an abnormal fetus. Such cases require preventive measures as well: before a future pregnancy is contemplated, the seminal fluid should be analyzed to determine whether the percentage of atypical sperm is within normal range.

On the other hand, the abortion may, of course, have been precipitated by an autonomic instability so great that minimal stimuli would provoke an extreme response. Moreover, such a tension state increases

with each failure to achieve childbirth, and each additional disappointment.

Therapeutic abortion

Psychiatric indications. With the increase in the incidence of therapeutic abortion a hardship has been imposed on hospital facilities faced with the task of interpreting the existing laws. Yet, both hospital and individual physicians have assumed responsibility for this task to an increasing degree. The previous, almost universal practice of permitting the individual physician to decide whether a patient's condition justified a therapeutic abortion has given way to the practice currently followed in most hospitals of basing this decision on committee action. There has been a gradual decrease in the number of legal abortions based on physical illness, such as tuberculosis or cardiovascular conditions, so that, with the exception of rubella at certain periods, psychogenic considerations are responsible for an ever increasing percentage of therapeutic abortions. The nuclear elements involved in therapeutic abortion are similar to the ones involved in contraception and sterilization.

Investigators have emphasized that therapeutic abortions are performed much more frequently on the private services than on ward services. Although the law usually permits interruption of pregnancy only to preserve the life of the pregnant woman, the fact is that the life of the prospective mother is almost never jeopardized by pregnancy, but her mental and physical health may well be, which, in turn, would jeopardize the proper development of the fetus. Nyswander, Klein, and Randall have emphasized these factors, as has Hall, in reports of findings in different national areas. And Guttmacher has pointed out that, while it is impossible to obtain therapeutic abortion incidence figures for the United States as a whole, current trends clearly indicate that there has been a change in philosophical orientation. The preservation of life no longer connotes merely organic survival; such decisions are now based on considerations pertaining to emotional adaptation.

Under the circumstances, it is not surprising that the incidence of therapeutic abortion on grounds of psychiatric illness has risen steadily so that it is now the most common single precipitating factor. This trend, which reflects current opinion that severely disturbed women should not bear children, also indicates an increasing concern with the welfare of children and an increasing awareness of the importance of early environmental and psychological factors for future development.

Incest or impregnation of a female who is mentally incapable of anticipating the potential results of coitus, rape, psychoses, and sufficient evidence that a child would be born mentally or physically defective are currently included among the psychiatric criteria for interruption of pregnancy.

Psychological effects. Whatever the circumstances,

the emotional effect of the abortion upon the woman represents a serious consideration. Although impregnation may occur in a female who has neither the knowledge nor the equipment to comprehend its significance, many conscious and unconscious factors are operative. While the woman may want to have the pregnancy interrupted, this wish may be accompanied by feelings of guilt and fear, and the abortion may, in such cases, precipitate a serious emergency reaction. Psychiatrists are generally agreed that certain safeguards should be established with regard to abortion and that the delineation of such measures is the appropriate responsibility of the members of this discipline, rather than the law.

Other Psychogenic Gynecological Problems

Other clinical phenomena frequently encountered, such as spontaneous abortion due to emotional factors; psychogenic aspects of contraception, including failure to use such measures; low back and pelvic pain; obesity; and psychogenic leukorrhea, are among the variety of additional syndromes included under the broad rubric which some authors have termed "psychosomatic gynecology." The basic psychodynamics involved in these symptoms vary from person to person. And given the same or similar psychodynamic patterns, there is a concomitant variation in the choice of presenting symptom or dysfunction. However, it may be speculated that the common denominators will include a faulty self-image and a faulty identification with the feminine role; fear of aggressive or competitive impulses; intense dependency needs and the frustration of these needs; and a fear of sexual feelings and penetration.

Today, women have an increased understanding of their problems in these areas, and this understanding, together with their greater cultural freedom, lessens the need for such distortions. Current medical efforts are directed to making childbearing equally safe for mother and infant. The good medical regimen, calling for frequent visits for examination, counseling, and psychophysical investigation, is designed primarily to prevent complications and thereby make later treatment unnecessary. Furthermore, this general approach is being extended to all aspects of female psychosexual function.

Suggested Cross References

For a further discussion of postpartum psychosis see Section 32.2. A more detailed description of the fundamental classical psychoanalytic concepts of the sexual development of females that were mentioned in this section may be found in Chapter 6, while alternate viewpoints regarding this subject are presented in Chapters 7 and 8, which deal with other psychoanalytic and psychodynamic conceptual models of personality and psychopathology. Normal sexuality is discussed in Section 5.7. Additional information regarding the relationship between sex

hormones and behavior can be found in Section 30.9 on endocrines. Legal aspects of abortion are discussed in Chapter 48 on forensic psychiatry, and sexual disturbances of children are treated in Section 41.6.

ROBERT A. CLEGHORN, M.D., D.Sc.,
F.R.C.P.(C.)

DAVID J. McCLURE, M.B., M.Sc.,
M.R.C.P.(I.)

In discussing endocrine malfunction, one must avoid any commitment to a concept of disease that prevents attempts to understand process by immobilizing symptoms into rigid syndromes. Alternatively, restricting discourse to psychosomatic terms may lead to indulgence in a convenient but nonenlightening semantic artifice. Psychosomatic medicine uses many models in research, and so the interplay of many different dis-

ciplines and methodologies is necessary for a multifaceted approach. Only by maintaining flexibility can the complexities of psychosomatic phenomena, including those of endocrine aberrations, be understood. The language of the various disciplines used must be employed appropriately. For example, Mirsky has pointed out that the physiological concept of homeostasis is not appropriate to human behavior, and biochemistry can give no information about the rigidity of the superego. His wise and succinct comments of particular relevance to psychoendocrinology state that psychosomatic medicine is

...an approach to the study of man which emphasizes that every scientific discipline provides concepts and techniques which are relevant to some particular level of organization; that no level of organization is more or less significant than any other; that a disturbance at any level of organization can influence all other levels; and that only the concomitant appraisal of all levels of organization can yield insight into the dynamic stability which characterizes health. This is an approach which emphasizes that every level of organization—from the social to the molecular—is involved in the predisposition, the precipitation, and the perpetuation of the various clinical derangements that plague man and his society.

Ultimately, psychiatrists are interested in the effects of malfunction of the endocrines as they affect people. (The anatomical, physiological, and neurological relationships are of great importance because of the principle of control by feedback mechanisms and because nervous system disturbances may be manifested by endocrine upset and vice versa.)

Hypothalamic Pituitary Function

Mechanisms. Emotional arousal may lead to a discharge of trophic hormones from the pituitary, with consequent secretion by the appropriate target glands, whose product in turn damps the mechanism causing the pituitary discharge. The secreted products from peripheral glands may also affect cerebral metabolism, leading to further disturbance in affect or cerebration. The hypothalamus is commonly named as the site of control, but most recent work indicates that the limbic system is intimately tied in with regulation of hypothalamic and other systems concerned in endocrine control. All this implies the principle of homeostasis in this physiological system.

Disorders

Hypothalamic lesions. These may result in pituitary dysfunction demonstrated by cachexia, obesity, dwarfism, eunuchoidism or regression in gonadal function, and diabetes mellitus or insipidus. These symptoms may occur singly or in combination with the attendant personality difficulties, such as the shy submissive adaptation of the eunuchoid. The group showing obesity, sexual infantilism, and skeletal abnormalities, such as broad pelvis and genu valgum have no detectable hypothalamic or pituitary pathology at autopsy; their condition was formerly termed

"Fröblich's syndrome," an eponym that should be dropped. Many mature normally at puberty and lose most of their stigmas. They are, however, subject to teasing and bullying in childhood and consequently to emotional distortion.

Pituitary disease. It can be accompanied by personality change in such conditions as dwarfism, which is not incompatible with normal intelligence and achievement of full adult role if genetic in origin but, if due to a pituitary pathology, may have associated endocrine defects of thyroid, adrenal, and gonads. The personality distortion depends, therefore, not only on the abnormal physical aspect but on the endocrine deficiency acting on the nervous system as well.

Acromegaly. This disorder leads to psychological repercussions due to the gross distortions of face and figure that occur. Studies at the Burghölzli Clinic indicated that half the observed cases had mild and the rest severe character changes. Thinking was retarded, and emotional expression was clumsy and slow. There is an apathy associated with a sort of inert elation. They are egocentric and resigned. Sex drive may be increased initially but is later diminished. Episodes of bad humor, thirst, or gluttony occur and appear to be compulsive. The psychopathology is not specific, according to Blickenstorfer. Psychoses are rare but do occur coincidentally. Acromegaly is not related to acromegaloïdism and is not an inherited disease.

Adrenogenital or virilizing syndromes and Cushing's disease. Though predominantly initiated by pituitary malfunction in most instances, these disorders are expressed largely through adrenocortical secretory activity and are discussed under "Adrenals."

Hypopituitarism. With hypopituitarism, adrenocortical deficiency may occur as a result of craniopharyngioma in preadolescence or as a chromophobe adenoma later. Pituitary cachexia, used synonymously with the eponym "Simmonds' disease" if restricted to the original description, is due to septic infarction of the pituitary following postpartum pelvic infection. If the pituitary defect is due to destruction allegedly ensuing on local vascular thrombosis as a sequel to severe hypotensive shock following uterine bleeding, it is known as Sheehan's syndrome. The symptoms in this kind of pituitary deficiency may resemble Addison's disease but with much less pigmentation, greater weight loss, and a fluctuating blood sugar level, which adds periods of suddenly impaired consciousness to the other physical symptoms and the psychological ones of inertia and impaired judgment. The most important distinction to be made is from anorexia nervosa, with which it is often confused. The latter condition is not hormonally dependent except insofar as the amenorrhea represents a hypothalamic-pituitary disturbance. Surgical hypophysectomy is the greatest of pituitary deficiencies, any one of which leads to a diminished emotional life and reduction—if not complete obliteration—of sexual drive.

Thyroid

Hyperthyroidism. The psychological manifestations of hyperthyroidism are present in almost every case and include anxiety, tension, physical and autonomic overactivity, and emotional lability, with depression, euphoria, or apathy occurring less frequently. More severe mental disorders also occur. Psychosis of the organic reaction type was common in severe cases with or without thyroid crisis before the introduction of antithyroid drugs. Now the delirium is more likely to be caused by the drugs themselves.

Other psychoses occurring concurrently include manic-depressive reactions, agitated depression, schizophrenia, and occasionally mania. The incidence of these psychoses in hyperthyroid patients is in dispute. A recent study by Bursten found 10 patients with psychosis and concurrent thyrotoxicosis among 8,000 patients admitted to a New York mental hospital. The conclusion drawn was that this combination was not a clinical rarity.

Etiology. There is wide agreement that psychological factors may determine the onset of hyperthyroidism, but there is no definite proof. Gibson found that severe emotional shock may precipitate the disease in genetically predisposed individuals, but, more significantly, prolonged tensions and chronic emotional stresses appear to be more important etiologically than acute episodes. The incidence of emotional precipitants was said by Lidz to range from 60 to 100 per cent, with an average of 80 per cent. Healthy people with a high I^{131} uptake show personality characteristics similar to those of patients with hyperthyroidism.

Psychoanalytical studies have postulated that there are specific similarities in the basic needs and defensive patterns in hyperthyroid patients, most of whom are women. According to psychoanalytic theory, there is in childhood an unusual emotional attachment and dependence on a parent, usually the mother, and any threat to this protection or approval is found intolerable. Often there is inadequate support given to the patient as a child because of economic stress, divorce, death, or multiple siblings. The persistent threat to security in early life leads to unsuccessful and premature attempts to identify with the object of dependence and cravings. Because of this failure, the patient continuously strives toward premature self-sufficiency and tends to dominate others by smothering attention and affection. There is a need in the patient to build defenses against a repetition of the unbearable feelings of rejection and isolation that occurred in childhood. Should these break down, then thyrotoxicosis may result.

Clinical features. The electroencephalographic (EEG) recordings in hyperthyroidism show an increase in the frequency of the α rhythm, the degree of change showing some relationship to the increase in the basal metabolic rate and the protein-bound iodine

levels. Following specific antithyroid treatment with radioactive iodine, the EEG in most cases reported by Wilson and Johnson became completely normal. There is, however, evidence to suggest that endocrinological factors other than thyroid play an important role in the production of EEG abnormalities in patients with hyperthyroidism.

Treatment. The adequate treatment of thyrotoxicosis requires a multidisciplinary approach. Initially, the metabolic disturbance should be corrected by appropriate medical antithyroid methods or by surgery. Symptomatic relief of agitation and anxiety can be obtained by means of sedatives and tranquilizers. Then, emotional factors that are important in the etiology of the disease can be dealt with by psychotherapy. The extent of the psychotherapy depends on the individual. Those moderately well adjusted emotionally before the onset of the thyrotoxicosis usually do well solely on a medical regimen, especially if their difficulties are resolved. Persons psychologically maladjusted before the illness began require psychiatric follow-up therapy; this is probably essential to prevent relapse and for successful long term treatment.

Hypothyroidism. Hypothyroidism with mental illness has been of interest to psychiatrists since Sir William Gull noted mental changes when describing the disease in 1873 and the Clinical Society of London in their report on myxedema in 1888 pointed out the high incidence of insanity as a complication.

Clinical features. Many personality disturbances have been wrongly attributed to the hypofunctioning of the thyroid. The incidence of severe mental disorder in hypothyroidism increases with the severity and duration of the condition. In most cases of myxedema, there is a progressive slowing of all mental processes, loss of interest, poor memory retention for recent events, unresponsiveness, impaired judgment, apathy, and tiredness unrelieved by sleep. Michael and Gibbons reported that excitement and irritability also occur. Disturbances in affect range from retardation to mania. Thought disorders, particularly of a suspicious or paranoid delusional nature, are common and may be accompanied by hallucinations. Many features of myxedema psychosis resemble the organic reaction types, with clouding of consciousness manifested as disorientation, confusion, or coma. It is not surprising to find organic symptoms, since the brain is affected by the thyroid deficiency in the general physical disturbance. Sassenbach reported that there is a relative cerebral hypoxia due to a decrease in cerebral blood flow and absence of change in the glucose consumption and mean oxygen requirements. These changes, noted Browning, are detected in the EEG as a slowing of the dominant frequency and a reduction in voltage.

Treatment. There is widespread belief that the mental symptoms caused by myxedema disappear when the patient is made euthyroid. This is not true. Recent investigations by Tonks indicated that some

cases with disturbance in consciousness and a history of less than 2 years are those most likely to respond favorably to the administration of thyroid. The other types of psychoses are less liable to show a lasting response to hormone replacement therapy and are best managed like psychoses of unknown etiology, that is, with psychotropic drugs. Asher has suggested that in these cases the mental changes are irreversible, but there is little evidence that this is so. It may be that all psychoses due to myxedema show organic features and that the psychoses that do not are, in fact, coincidental. It is considered unlikely that emotional factors are important in the production of myxedema.

Parathyroid dysfunction. Psychiatric disorders occur with parathyroid dysfunction as with other endocrine upsets. The symptoms associated with hypoparathyroidism are those of a toxic delirium. Anxiety, agitation, and depression are common; delusions and hallucinations usual; disorientation, confusion, and delirium are frequent; paranoid ideas and suicidal attempts may occur.

Neuropsychiatric disorders in primary hyperparathyroidism have been reviewed in detail recently by Schwartz. In one third of 31 cases surveyed, symptoms of nervousness, tension, and irritability were found. Retarded and agitated depressions and a confusional state were encountered in individual cases. Signs correlated with serum calcium levels. Therapy relies on medical and surgical treatment of the underlying condition.

Pancreas

Diabetes mellitus. The importance of the emotions in diabetes mellitus has been given variable weight over the years. They were thought important until the present century, when a series of events nullified the earlier interest. These were: advances in knowledge of the physiology of carbohydrate metabolism and the beneficial effects on the prognosis and treatment of the condition with the introduction of insulin; the acceptance of heredity as an adequate etiological explanation; and the failure of combat in World War I to increase significantly the number of diabetics. However, the rise of psychosomatic medicine over the last 25 years produced a revival of interest in the complex psychological aspects of the disease.

Etiology. Heredity plays a dominant role in the etiology of diabetes. A child from a diabetic-non-diabetic marriage has a one-in-four chance of developing diabetes, predictable genetically by the Mendelian ratio. If both parents are diabetics, diabetes in the offspring is inevitable. Nevertheless, cases develop in which no hereditary taint can be identified. Many observers, such as Lidz, have noted cases in which the onset coincided with or closely followed emotional disturbances. These situations can only be assessed in terms of personality organization, needs, and defenses, since other people survive what seems like

comparable trauma. That diabetes mellitus may arise from emotional causes is a distinct possibility, but one that is not readily susceptible to proof, said Treuting.

✓ **Psychophysiology.** There is more understanding and agreement about the role of emotional factors in established diabetics. Under experimental stressful situations, various changes have been demonstrated by Hinkle and Wolf. These include ketonemia; alterations in the fasting blood sugar level, leading to either hyperglycemia or hypoglycemia; changes in the glucose tolerance curve; and an increase in the excretion of water, glucose, and chlorides. The stressful life situations that produce these metabolic changes appear to have a high degree of specificity for the individual and usually involve significant persons in their lives, such as parents, spouses, or children. Circumstances that provoke feelings of frustration, loneliness, or dejection are frequently accompanied by glycosuria and increased insulin requirements. Conversely, resolution of conflicts and life situations to which the diabetic responds with feelings of security and contentment are often accompanied by hypoglycemic reactions, with a decrease in glycosuria and reduced insulin requirements. Patients repeatedly admitted to a hospital in diabetic acidosis either have abandoned their therapeutic regimen or have omitted to take their insulin because of emotional disturbances. In this way, they use their diabetes as a manipulative tool to escape into the hospital and so avoid the environmental stress.

✓ **Psychological characteristics.** The effects of diabetes on the patient create psychological problems that may result in behavioral difficulties. Children develop temper tantrums when desirable foods—like candies, jams, and desserts—are withheld from them. Adolescents, with dietary and recreational activity limitations, feel different from their peers and may be considered asocial by them.

Parental reactions to the disease are important in molding the future personality structure of young diabetics. Anxiety in the parents is quickly transmitted to the patient; perfectionistic mothers gain control of the illness at the cost of behavioral difficulties.

Each patient is required to make his own individual adjustment to the numerous anxiety-provoking factors associated with the disease. These include dietary restrictions, self-administration of hypodermic injections of insulin, daily urinalysis, the effects on employment and marriage prospects, and the stigma of suffering from a chronic incurable disease. The well adjusted patient responds by self-restriction and rigid control of his diet, but those with low frustration tolerance show total disregard for food restriction by overeating and developing provocative and delinquent attitudes toward their diets.

Obesity and actual weight gain are accepted as predisposing and precipitating elements, respectively, in diabetes. Diabetic patients may have a compulsive

desire to eat, and this is intensified during periods of loneliness, dejection, or tension. Overeating is regarded as a psychological substitute for affection, and terms such as "oral," "dependent," "seeking maternal attention," and "passive" have come to be associated with the diabetic personality, but they are obviously not specific. In general, diabetes tends to impede the maturation processes in children and to favor regression in adults.

✓ **Management.** The proper management of diabetes mellitus requires an adequate understanding of the personality traits and life situation of the individual patient. Education in the difficulties of a restricted diet and techniques of insulin by a competent and cheerful physician helps to alleviate anxiety. Since obesity is usually caused by underlying emotional problems, group psychotherapy may be a good way of dealing with it. Summer camps provide an excellent means of handling diabetic children. There, the child receives supervision and instruction about his diabetes, which helps him to become self-reliant and to lose his feelings of isolation. Impotence and infertility occurring in the diabetic are, said Schwartz, due to an associated hypogonadism, though psychological factors may often be chiefly responsible. The symptoms of weakness and fatigue in hypoglycemia may cause it to be confused with anxiety states. It may also mimic a catatonic stupor. Glucagon deficiency and hyperinsulinism from exogenous or endogenous sources may be responsible.

Gonads

Gonadal function begins in utero with differentiation of genital structures and neural tissues that control behavior in experimental animals. The studies of Young and of Goy indicated that a normal embryological pattern of the sex hormones is necessary for the postnatal development of normal sexual behavior patterns and normal social relationships. In adult animals, hormones elicit mating response patterns by acting on brain mechanisms. In the mature human, androgens are chiefly responsible for sexual drive or libido in both sexes. Experiential factors modify innate sexual patterns in animals and even more so in man. The studies of the Hampsons and of Money of hermaphrodites indicated that the gender role is acquired in the first 3 years of life and is maintained despite incongruities with respect to chromosomal, gonadal, and hormonal factors, or internal or external morphology. This is relevant to the problem of homosexuality, which is not dependent on hormones.

Testes. The coincidence of puberty and schizophrenia suggests a causal relationship that is, however, not supported by modern endocrine studies. Atrophy of tubules and aspermatogenesis, observed by Mott and Prados, have been both denied and affirmed. No significant pathognomonic endocrine pattern is characteristic even of a small group of schizo-

phrenics, but some suggestive findings remain, and more refined techniques may yet reveal participation of hormones in this obscure malady.

Hypogonadism. This disorder has characteristic physical manifestations that may be alleviated in large part by various androgenic preparations if the condition is due to a testicular fault. Obviously, the alleviation is more apt to be complete if treatment is begun soon after the gonadal failure. Delayed puberty or testicular regression due to pituitary malfunction may respond to treatment with human chorionic gonadotropin, noted Williams. The endocrine pattern, especially during the developmental period, may have profound psychological effects. The studies of Bleuler suggested that individuals who do not have normal gonadal development during childhood fail to achieve normal heterosexual object relationships. Hypogonadal adult males tend to be passive and constricted psychosocially. Failure to develop sexual drive at a normal age for puberty is accompanied by emotional crippling. Later restitution of such drive may be more anxiety-provoking than satisfying. Paranoid reactions are a frequent response to the physical defects of eunuchoidism and such accompaniments as feminine appearance, including gynecomastia, noted Schwartz.

The hypogonadism of Klinefelter's syndrome, due to a chromosomal abnormality that accounts for the defects, has attracted much attention of late. Some such individuals attain a normal or above average mentality, but most are below.

Impotence. Impotence may be a manifestation of defective androgen secretion in eunuchoid males but not in normal males, in whom psychogenic causes are almost solely responsible, the exceptions being severe illness and starvation. Differences in sexual drive may be genetically determined in animals, and clinical observations indicate that there may be considerable differences in the amount of duration of sexual drive in the human also. Androgenic preparations can have only a placebo effect in psychogenic impotence.

Male climacteric. Male climacteric with vasomotor manifestations, corresponding to that in women, is rare. Williams noted that it may be seen when pathological processes interfere with Leydig cell function.

Ovaries. The influence of the ovaries on physical and mental maturation and reproductive functions represents a complicated interplay between hormonal action and feminine psychodynamics.

Ovarian malfunction. Malfunction of the ovaries may take many forms. Infantilism due to ovarian failure, whether primary or secondary to a pituitary defect, has psychological repercussions eminently manifested during adolescence, when comparison with peers makes for anxiety and withdrawal. Precocity in development of sexual characteristics can likewise be embarrassing, though less negatively disturbing. Cosmetic aberrations, such as acne of adolescence, can be torture, and hirsutism with or without signs of

androgeny is also distorting to the personality, noted Rome and Robinson.

Menstrual disorders. Dysmenorrhea is dependent in a large proportion of cases on a neurotic personality configuration, including resentment of the feminine role, overdependency, sensitivity to stress, and other distortions. There is an extensive literature but little concept of prevalence or its significance in healthy women.

Menorrhagia, metrorrhagia, and amenorrhea occur as part of personality disorders and inappropriate response to stress. Only by ascertaining the full picture of the patient's life situation from her and from reliable informants can a picture of the pertinent fears and conflicts be obtained. Patient psychotherapy with assistance from the endocrinologist may save the individual from needless and mutilating surgery.

Premenstrual tension and depression may exist as a single complaint or may accompany other gynecological or psychiatric symptoms. This is probably the most prevalent of the psychosomatic endocrine disturbances. Many treatment approaches have been suggested, including the use of diuretics and sedatives, hormone therapy, phenothiazines, and intensive psychiatric appraisal and treatment of the underlying personality disorders.

Sterility and repeated abortions. These may be manifestations of endocrine malfunction arising from emotional disturbances. Again, full information about the person and her situation is necessary for assessment and technical studies. Psychotherapy in such cases has been demonstrably effective.

Menopause. The menopause has been unjustly blamed for psychiatric ills. It is, indeed, an event of psychological significance, particularly for the unfulfilled. Neurotic and psychotic events at this time of life demand the same kind of careful psychiatric inquiry as at any other. The menopause cannot account for events that may be psychoneurotic, schizophrenic, manic-depressive, or hysterical in nature.

Postpartum psychoses. These may be schizophrenic or depressive; they may constitute a single episode or be repeated with each pregnancy. The changing hormonal milieu may be critical for predisposed persons, but the altered psychological status may be the most important factor in the psychologically brittle or immature.

Adrenals

The interaction between the emotions and the activity of the hypothalamopituitary adrenocortical system has been investigated in normal subjects and psychiatrically disturbed individuals. The response of the adrenal cortex in normal persons was studied under stressful situations, such as in relatives accompanying patients to the emergency rooms of general hospitals; students just prior to their final examinations; and patients awaiting major surgery. The com-

mon response to these stressful situations was an increase in the levels of plasma cortisol and the excretion of urinary corticosteroids.

Addison's disease. In his original description of the disease in 1855, Addison noted the presence of psychological symptoms, but it was not until 1941 that Engel and Margolin described the nature and frequency of mental symptoms in this condition. These were confirmed by Cleghorn and extended by Stoll. Apathy and negativism appear in four fifths of cases, depression and irritability in one half, suspiciousness and agitation in about one sixth. The symptoms, though worse in crises, improve only slightly following treatment with electrolytes and deoxycorticosterone, but with cortisone or allied compounds there is substantial improvement. Paranoid and catatonic states and manic-depressive psychoses may be seen in some 5 to 10 per cent of untreated cases and usually respond to glucocorticoid treatment. Manic and depressive states with paranoid coloring and occasionally vivid hallucinations may also occur as a response to early treatment with cortisone or its congeners.

The electroencephalogram shows abnormalities in Addison's disease, the pattern being one of slow diffuse activity at two to six cycles per second. Since correction of the electrolyte imbalance does not abolish this abnormality, it seems to be unrelated to sodium and potassium changes. Cortisone-type therapy restores the EEG picture to normal.

Cushing's syndrome. The psychological manifestations of Cushing's syndrome were formerly considered to be a reaction to the associated physical deformities, but they often appear before noticeable physical changes occur. Their incidence is roughly 50 per cent in the naturally occurring disease, where they usually appear much more slowly than in the therapeutically induced syndrome. A wide variety of psychiatric symptoms have been reported. Depression appears most frequently and is often associated with anxiety or retardation. Episodic outbursts of disturbed behavior, with excitement and acute anxiety verging on stupor, are also met. In general, a typical schizophrenic reaction is not seen, although paranoid delusions and auditory hallucinations do occur in some cases. The more severe psychiatric symptoms can often be managed with judicious use of phenothiazines.

Adrenocorticotrophic hormone (ACTH). ACTH, cortisone, and related substances are administered to patients with a variety of diseases, often in amounts that are not sufficient to produce a characteristic clinical picture of Cushing's syndrome. The side effects in terms of psychological symptoms deserve special comment. The commonest finding, noticed shortly after their introduction into medical treatments in the early 1950's, is an alteration in mood, principally euphoria; depression also occurs, but less often. Other transient findings are tension, restlessness, and excitability. Psychotic symptoms are less common but

take the form of mania, delusions, hallucinations, disorientation, and catatonic states. The clinical picture, therefore, is sometimes indistinguishable from acute paranoid schizophrenia, acute catatonic schizophrenia, or acute organic psychosis, except that on most occasions the condition is reversible when the hormone therapy is stopped. In recent years these incidents have not been reported because they are easily controlled by reducing the dose of the drug.

The high incidence of depressive features in Cushing's syndrome can be contrasted with the high incidence of euphoria occurring in those on hormone therapy. The reasons for these contrasting findings are as yet unclear. Symptomatic relief of psychotic reactions can sometimes be effected with judicious use of phenothiazines.

Adrenal function in the psychiatric disorders

Anxiety. Persky et al. published the results of their extensive investigations on patients whose predominant symptom was anxiety. Their findings showed that the activity of the adrenocortical system in anxious individuals reacted similarly to that of normal subjects in stressful situations. They also found that radioactive cortisol had a higher turnover rate in those with anxiety than in normal persons, indicating that cortisol is produced in larger amounts and metabolized faster in anxious subjects.

Schizophrenia. It is not surprising when one considers the complex nature of the schizophrenic illness that conflicting results have been obtained by different investigators who were measuring the activity of the adrenal cortex in these patients. However, it has been shown by Bliss et al. that acute schizophrenics who are emotionally disturbed appear to have elevated plasma cortisol levels (17-hydroxycorticosteroid levels), whereas chronic cases with little or no affect have levels comparable to normal emotionally calm subjects. One investigator has recently indicated that the excretion of 17-ketosteroids is higher in schizophrenic patients who have not regressed than in those who have.

Depressive states. The suitability of depressive illness for the study of adrenocortical activity in relation to emotional stress is apparent: it is a common illness, and the majority of depressed patients recover or improve within a comparatively short time. Original work on depressed subjects was carried out by the Michael Reese group in 1956 and 1957. Their findings showed elevation of 17-hydroxycorticosteroid levels in the plasma; the more severe the depression, the higher the corticosteroid levels. Higher cortisol values were seen in the retarded depressions than in the agitated ones. Gibbons and McHugh reported a positive correlation between the severity of the depressive illness and the height of the plasma cortisol levels, with the majority of patients showing a decrease in the cortisol levels with clinical improvement or recovery. These findings were confirmed at

the Allan Memorial Institute by McClure, who also observed that the plasma cortisol levels remained elevated throughout the 24 hours in these patients. Gibbons, using radioactive cortisol to determine the adrenocortical secretion rate, confirmed the increased adrenal activity in depressed subjects and demonstrated that there was a high correlation between the elevated plasma cortisol levels and the cortisol secretion rate.

Mania. Knowledge of the adrenocortical response in mania is still small, but it is gradually increasing, chiefly through the reports of investigators on individual cases. Rizzo et al. found low urinary glucocorticoids in a manic-depressive female patient during her hyperactive episodes, with the levels returning to normal after clinical recovery. Gibbons and McHugh reported a case with high blood plasma-cortisol levels during phases of depression and low levels during phases of elation.

Psychiatrists such as Lewin have suggested that mania is a defense against the pain of depression. Bunney et al. attempted to find biochemical confirmation of this psychological theory. They simultaneously studied the behavior and the urinary 17-hydroxycorticosteroids in a female patient with regular 48-hour manic-depressive cycles over a 2-year period. The patient's mania was characterized by intense denial of her illness and was accompanied by low 17-hydroxycorticosteroid levels. Her days of depression were associated with feelings of suffering and pain, but her 17-hydroxycorticosteroid levels were high. The investigators feel that these findings support the concept that the mechanism of denial is associated with low levels of urinary 17-hydroxycorticosteroids.

Adrenogenital syndrome. Hermaphroditism is frequently due to overactivity of the adrenal cortex in utero. When the overactivity of the adrenal cortex occurs after puberty, it may lead to Cushing's syndrome or the development of a simple state of hirsutism, clitoral hypertrophy, and menstrual irregularities. Considerable psychological changes, such as depression and self-consciousness and even paranoid psychosis with delusions and hallucinations, may also appear, but in the cases where androgenic reaction exceeds the corticoid, there seems to be less mental disturbance. There have been claims that these people have been restored to normal by an adrenalectomy.

Differentiation from Cushing's syndrome can be made through a study of ketosteroid and corticoid excretion in the urine. Actually, the two syndromes may merge with each other. The incidence of mental abnormality seems to be much greater in the typical Cushing's syndrome, which is associated with a much greater degree of increase in the glucocorticoid secretion.

Idiopathic hirsutism is often an obscure phenomenon without any adequate explanation. Its occurrence is naturally disturbing to the individual, and

it is said that the incidence of hirsutism is greater in female schizophrenics.

Adrenal medulla. Modern biochemical techniques have greatly enhanced knowledge of the products of the adrenal medulla and of sympathetic neurohumors. These substances are: dihydroxyphenylethylamine (dopamine), norepinephrine, and epinephrine. The first two are the predominant "sympathins"; the last two make up most of the adrenal medullary catecholamines; norepinephrine is the transmitter substance released from sympathetic postganglionic nerve endings. The relation of these compounds to nervous and mental diseases is a matter of controversy and has been reviewed in Sourkes' authoritative book.

Relation to emotions. Because of the differences in pharmacological effects of norepinephrine and epinephrine and because of their differential release action, Funkenstein expected that each might function as the mediator of different patterns of emotion or of personality. Elmadjian et al. studied individuals undergoing various types of stresses, both naturally occurring and experimentally induced, and interpreted their results as showing that active aggressive emotional displays are related to norepinephrine secretion; tense, anxious, and passive individuals show an increased excretion of epinephrine and a normal excretion of norepinephrine.

Although some other investigators have obtained conflicting results, Mendelson found no changes in the catecholamine output during the stress of prolonged sensory deprivation, and negative results were found when medical students were shown moving pictures with emotion-laden content. Men having a high incidence of coronary artery disease and showing much ambition, who had to meet deadlines under intense pressure, were found to have a rising excretion of catecholamines, particularly norepinephrine, during working hours. Subjects with the opposite type of behavior excreted less.

Mason studied monkeys provoked to an emotional response and found that the release of epinephrine was related to the element of unpredictability in the experimental situation. One can only conclude from this work that the hypothesis is quite unproved that human beings can be characterized by their catecholamines.

Relation to mental disorders. In the psychoses and other mental abnormalities, some changes in catecholamine metabolism have been encountered, none of which appears to be decisive for the clinical condition. The only exception appears in the subnormal level of epinephrine that Weil-Malherbe found in mental deficiencies. In manic-depressive patients, abnormal excretory patterns have been observed. The excretion of the catecholamines is higher during the manic phase of the psychosis than during the depressive phase. The excretion of epinephrine may be elevated in acute schizophrenic patients but is normal in chronic cases. Abnormally low rates of

excretion of epinephrine were observed in patients with senile dementia and with Down's disease (mongolism). In a study of acutely disturbed patients admitted to a hospital for treatment, it was found that those showing mainly depression tended to excrete a somewhat greater amount of norepinephrine than the normal control subjects; those showing anxiety had an elevated output of adrenocortical hormone; and patients with agitated depression had an increase in both corticoids and epinephrine. Such results suggest that psychic stress does not lead to a uniform pattern of hormonal reaction but may show a variety of patterns.

Relation to brain damage. Many groups of psychiatric investigators have been engaged in the search for an amine or amine metabolite that is toxic for brain tissue, producing a psychosis. The effects of mescaline, lysergic acid diethylamide (LSD), and similar agents constitute the theoretical model for these endeavors. It has been suggested that the toxic substance is adrenochrome, adrenolutin, or some related aminochrome derived from epinephrine. However, scientific proof has not been forthcoming. Recently, Friedhoff and Van Winkle have put forward a claim that an abnormal metabolite of dopamine is related to schizophrenia. This metabolite is dimethyldopamine or 3,4-dimethoxyphenethylamine. This substance is among a number of congeners that cause a catatonic syndrome in cats. At present, many groups are engaged in determining the specificity, or lack of it, of dimethyldopamine and its derivatives for mental disease.

The best evidence for catecholamine dysfunction in cerebral disease comes from studies of Parkinson's disease. Dopamine, which is normally present in relatively high concentrations in some of the basal ganglia of the brain, is deficient in these masses of gray matter at post-mortem examination of Parkinson's disease patients. Norepinephrine and serotonin are also low but not to the same extent. Urinary excretion of dopamine is also subnormal in this disease, indicating that the metabolic defect, whatever it is, may express itself generally as well as in the brain.

Poirier and Sourkes have prepared monkeys with specific unilateral lesions in the region of the substantia nigra as experimental models of basal ganglial disorder. Such animals exhibit deficient dopamine or serotonin or both in the ipsilateral striatum. The neurochemical changes correspond not only to lesions of specific tracts but to the occurrence of specific neurological changes, detected as tremor, abnormal posture, or both, of the contralateral limbs.

Pheochromocytoma is a tumor of chromaffin tissue, occurring usually in one of the adrenal glands but sometimes ectopically. The neoplasm can release catecholamines spontaneously, provoking a rise in blood pressure, palpitation, headache, vertigo, and anxiety. These patients occasionally come to the attention of

the psychiatrist and may receive the diagnosis of psychoneurosis before the tumor is discovered.

30.10 ALLERGIC AND SKIN DISORDERS

W. D. ENGELS, M.D.

ERIC D. WITTKOWER, M.D.

Skin Disorders

The situation of the skin at the interface of the organism and its environment probably accounts for its very early recognition as an important somatic sounding board for the emotions. Expressions such as

"crimson with rage" and "white with fear" long antedated any formal exposition of psychosomatic concepts. Interest in the psychological aspects of skin disorders can be traced back as far as 1891, when Brock and Jacket coined the term "neurodermatitis."

Psychophysiology. As a major component of the body's homeostatic defensive system, primarily involved in heat and fluid regulation, the skin well illustrated Cannon's concepts of adaptation to environmental change. He described the blanching of skin under the stimulus of fear as an instance of his fight-flight principle—constriction of the cutaneous vascular bed in order to shunt blood preferentially to the musculature.

As the organ system most visible to inspection, the skin serves as a mirror of emotional states. Because of its rich endowment with sense receptors for pain, touch, and temperature sensations, the skin becomes the matrix for the body ego. The importance of physical contact in early development has been demonstrated by Harlow in monkeys and by Bowlby in children. The sexual function of the skin and the significance to normal development of its successively libidinated erogenous zones was hypothesized much earlier by Freud.

Abnormal cutaneous sensations

Generalized pruritus. It has been shown that itch, tickle, and pain are sensations all conveyed by the same outgoing fibers and are differentiated only by the frequency of impulse. Although release of histamine and proteinases into the skin has been proposed as the mechanism by which this sensation is initiated, other researchers, such as Rothman and Arthur and Shelley, have cast doubt on these theories. At present, the neurohumoral basis of naturally occurring pruritus is still unclear.

Anxious and tense individuals or a normally well adjusted individual at times of anxiety and tension may be more conscious than usual of itching sensations from a given lesion. Guilt, anger, boredom, irritation, and sexual arousal may all predispose the individual to itching and subsequent scratching. Experimental manipulation of the itch threshold with psychic stress has been demonstrated by Cormia. His subjects, under conditions of emotional tension, received previously standardized doses of histamine intradermally and showed an enlargement of the wheal and flare response and a prolongation of itching.

Kepecs and Robin developed a carefully standardized stimulus—stroking the skin with cotton wool for a 2-minute period—and were able to correlate the interpretation of this stimulus—itch, tickle, touch—with personality factors of the subjects:

The pain-pleasure series (pain, itch, tickle) is closely related to erotic instinctual life. The touch system is related to and subserves ego functioning. Responses of normal adaptation appear related to optimum balance between erotic, instinctual life and ego control, insofar as this can be reflected in the skin.

Reactions of no adaptation (all itch or tickle) indicate excessive emotionality and deficient control. Reactions of touch only are correlated with attempts at excessive and rigid control of affects.

Scratching evidently derives from reflexive movements that serve to clear the skin of irritants. In humans it may be both painful and highly pleasurable and may thus serve both self-punitive and autoerotic purposes. Musaph in a recent monograph entitled *Itching and Scratching* also pointed to the role of itching as a derived activity. He referred to the concepts of Tinbergen and other ethologists who observed that most animal species, when in the midst of conflicting drives, respond fully to one and make some token response to the other in what is called a derived activity. Musaph then pointed to scratching as just such an activity, frequently serving as a derived expression of frustration.

Localized pruritus

Pruritus ani. The investigation of this disorder commonly yields a history of local irritation—threadworms, irritant discharge, fungal infection—or general systemic factors, such as nutritive deficiencies or drug intoxications. However, after running a conventional course, it often fails to respond to therapeutic measures and acquires a life of its own, apparently perpetuated by scratching and superimposed inflammation. It is a distressing complaint that often interferes with work and social activity. Careful investigation of large numbers of these patients has revealed that personality deviations often precede this condition, and emotional disturbances often precipitate and maintain it. Some workers have postulated specific psychic factors in pruritus ani patients and feel that many character traits of these patients are based on compliance with or opposition to parental dictates regarding bowel training. Fixation at or regression to this anal stage of development leads to conflicts that frequently involve sadistic impulses. These, being intolerable, may be dealt with by a variety of defenses: (1) reaction formation manifesting as gentleness and subservience toward authority, (2) projection with suspiciousness and ideas of reference, (3) turning on the self, of which the scratching is a vivid manifestation.

A pleasurable component of the anal activity—rubbing, manipulating—is usually, though not invariably, obliterated by an unconscious sense of guilt, which changes the pleasurable rubbing into self-punitive scratching. Characteristically, patients susceptible to this illness display other evidences of their pregenital level of development, and in both men and women defective heterosexual relationships are common. In line with the anus as a site of expression of conflict over latent homosexuality, a preponderance of pruritus ani in men is noted.

Pruritus vulvae. As in the foregoing condition, specific physical causes, either localized or general-

ized, may be demonstrable, and the presence of glaring psychopathology in no way lessens the need for adequate medical investigation. Studies of large numbers of such patients suggest that both itching and scratching have a painful and pleasurable quality. In some patients, pleasure derived from rubbing and scratching is quite conscious—they realize that it is a form of masturbation—but more often than not the pleasurable element is repressed. Some investigators feel that the disorder is seen in patients with a characteristic history and psychodynamics. Most of the patients studied gave a long history of sexual frustration, which was frequently intensified at the time of the onset of pruritus. For many of these patients, the coexistence of a powerful father fixation and a severe code of morality interfered with adult sexual expression and in some cases led to pronounced masochistic trends.

At times of intense frustration, then, these patients regress to a masturbatory level of psychosexual development, but, because of their intense guilt, self-punitive feelings also become intense. Thus, the pruritus vulvae strikes a balance between pleasure and pain.

Abnormal cutaneous manifestations

Hyperhidrosis. States of fear, rage, and tension can induce an increase of sweat secretion. It has been demonstrated by Cuno et al. and Herman et al. that perspiration in the human is of two distinct forms, thermal and emotional. Emotional sweating appears primarily on the palms, soles, and axillae; thermal sweating is most evident on the forehead, neck, trunk, and dorsum of hand and forearm. The sensitivity of the emotional sweating response serves as the basis for the measurement of sweat by the galvanic skin response, an important tool of current psychophysiological research.

Excessive sweating (hyperhidrosis) may, under conditions of prolonged emotional stress, lead to secondary skin changes, rashes, blisters, infections, etc., and may thereby underlie a number of other dermatological conditions that are not primarily related to emotions. Basically, hyperhidrosis may be viewed as an anxiety phenomenon mediated by the autonomic nervous system, although it must be differentiated from drug-induced states of hyperhidrosis.

Rosacea. This condition is more common in women than in men and usually occurs in the thirties and forties. It features an increased vascularity, with papule formation on the blush area of the face and upper chest. Sufferers from rosacea display a heightened responsiveness not only to heat but also to hot drinks, spiced food, hurried meals, and a variety of emotions. Most patients in a large series studied by Wittkower related that excitement and worry, among other factors, brought on hot flushes. They displayed variations in the severity of rosacea in connection with changes in their life situation—work versus holi-

days, health versus illness of relatives. Some workers feel that these patients present specific personality features, the most outstanding characteristics of which are their abnormally high level of self-esteem, anxious dependence on the good opinion of others, compulsive desire to please, and constant fear of attracting attention. Underlying these were unreasonably strong feelings of inferiority, guilt, and shame. In most of the patients studied, rosacea was preceded by life situations that led to the production or activation of shame. For these people, the rosacea appeared to represent a state of permanent blush.

Urticaria. Many physical, chemical, and biological factors have been incriminated as causative of urticarial eruptions; however, emotional stresses and, particularly in chronic urticaria, personality disorders are clearly present in a high percentage of cases.

An extensive literature documents the precipitation of the onset and relapses of urticaria by emotional disturbances. Kreibich and Sobotka reported a patient who displayed such attacks when he was annoyed. As a test of this correlation, he was hospitalized and on two occasions wrongly accused of some minor irregularity by the nurse. In both instances he became annoyed and within a few minutes broke out in an urticarial rash. Hansen reported the case of a woman dining on lobster in a clandestine meeting with her paramour. There, they were surprised by her husband, and the woman developed a generalized urticaria. Though never sensitive to lobster before, she subsequently suffered from urticaria whenever she ate it. Stokes, Kulchar, and Pillsbury detected a relative psychogenous stress in 83 per cent of 100 patients studied for urticaria. Many other authors have undertaken detailed investigations of the precise emotional meaning of precipitating events. A particularly thorough discussion of emotional precipitants is to be found in a recent publication by Musaph.

Study of 35 urticarial sufferers permitted Wittkower certain conclusions about the group as a whole. Two thirds of this group stated spontaneously that, as children, they had been deprived of their mother's love. In the majority of cases this belief seemed to be ill-founded, a reminder that the adequacy of any commodity, including maternal affection, depends not only on sufficiency of supply but also on intensity of demand. As children, they responded to frustration in one of two ways. Some openly expressed their resentment; others suppressed or repressed the aggressive response, and, indeed, turned to its opposite—exemplary, compliant behavior—in order to secure from the environment the affection for which they felt such a strong need.

These two behavioral patterns were carried forward into adult life, with roughly half of the patients displaying an ingratiating and excessively compliant attitude toward their environment, an attitude that

was further intensified by criticism or disapproval. The other group, far from begging for what in fact or in fantasy had been denied them, demanded what they regarded as their due, complained bitterly if it was not forthcoming, and in general presented a vindictive and bellicose appearance. The aggressive behavior of the latter patients arose from a number of sources. For one, they were quite unable to tolerate any denial of love or affection; for another, they assumed an aggressive defense because of their inability to admit their inordinate need for affection; and thirdly, it appeared that at least some of them compulsively repeated the childhood trait of seeing just how far they could go without being rebuked, perhaps in the hope that they would be loved despite their objectionable behavior.

Despite glaring differences of conduct, patients of both groups showed in common an inability to tolerate the denial of love and reacted with anger to such a situation. It found token expression in urticarial eruptions. This expression of infantile anger seems to be central to the development of urticaria.

Atopic dermatitis. Of the many diseases in the eczema-dermatitis group, atopic dermatitis has long been regarded as the one most strongly influenced by the emotional life. It is usually accompanied by itching that often appears disproportionate in severity to the visible lesions. Some authors have considered the itching to be primary and the skin lesions a reaction to scratching. For this reason, it is often called neurodermatitis.

This condition is found in both a childhood and an adult form, both frequently appearing in the same individual with an intervening period of several years. The term "atopic" signifies that it is regarded as an allergic disorder, but the specific interrelationship of allergic and emotional factors is far from clear.

As with urticaria, a study of events and circumstances at onset reveals a preponderance of emotionally significant events. The literature abounds with references to the appearance of atopic dermatitis following an emotional disturbance. In 77 of 90 patients studied by Wittkower and Edgell, events of a disturbing nature preceded the onset of dermatitis, and 147 episodes were discerned in which onset, relapses, or aggravations were clearly related to emotionally disturbing situations. The recurring theme that seems to pervade all the varieties of precipitating events is that of loss of love. This can be undisguised or so heavily disguised as to be indistinguishable as such until one is well acquainted with the history and dynamics of the individual.

Are there personality qualities and emotional states that specifically seem to characterize the victims of this illness? Patients studied by Wittkower and Edgell felt that they had not had their fair share of affection as children and tended to maintain in adult life an inordinate childlike dependence on their parents, in most cases the mother. As in the cases

described for urticaria, various responses were possible. For some, a need for affection, attention, and support found its expression in a submissive, docile, or even overtly helpless attitude. In others, the same need was concealed behind self-assertive, ambitious, or even provocative behavior. For many, the lack of self-confidence impaired their social and occupational progress. Many remained single or married partners who appeared to serve as parent substitutes. One 45-year-old man could only resist the urge to scratch himself if his motherly wife sat with him and held his hand.

Wittkower and Hunt studied atopic dermatitis in children. Scrutiny of the child-parent relationships stressed the factor of maternal rejection, a rejection that could be either overt or disguised beneath a reaction formation of intense overprotectiveness. The latter form appeared to be the most common and was stressed by Miller and Baruch, Williams, and Newell. Abramson referred to an engulfing attitude in the parents of eczematous children wherein the parent demands narcissistic satisfaction, regardless of any danger to the child. Thus, simply stated, in somatically susceptible individuals rendered emotionally vulnerable by childhood experience, events that reactivate feelings of longing for love are found to precipitate the onset and exacerbations of atopic dermatitis.

Psoriasis. The primary cause of psoriasis is not known, but a number of aggravating factors have been well established. These include systemic infections, an excess or deficiency of sunlight, damp, cold, and emotional stresses. In contrast to the preceding conditions, psoriasis does not appear to be a specific affect equivalent but responds unspecifically to a variety of emotional stresses. It does not seem to be bound to any personality type or any specific conflict constellation, but in one large study the number of emotionally maladjusted individuals was found to be far in excess of the normal population. For these individuals, the nature of the emotional event that proves significantly stressful is, of course, related to the particular personality difficulty. If an individual is emotionally maladjusted for reasons unrelated to the psoriasis, the emotional maladjustment may, but need not, take charge of the psoriasis and may determine its onset and further relapses.

Psychodynamics. It can be seen that certain emotional states appear to correlate highly with various forms of cutaneous disorder: aggression with generalized pruritus, sexuality (both heterosexuality and homosexuality) with genital and anal pruritus, anxiety with hyperhidrosis, shame with rosacea, anger with urticaria, and the longing for love with atopic dermatitis.

None of these mood states is disease-specific; all are found not only in normals and psychoneurotics but also in other psychosomatic disorders. For example, the longing for love, which seems to be asso-

ciated with atopic dermatitis when coddling or fondling is the regressive object, may be expressed in gastric hypersecretion if food is the regressive object.

Finally, it should be stressed that none of the disorders described is considered to be, strictly speaking, psychogenic. All are multicausal and determined by a combination of constitutional and acquired factors, of which the emotional is but one—one weighing more or less heavily in the given individual and in the individual at a given time.

Allergic Disorders

In the preceding pages, evidence was submitted indicative of the relevance of emotional factors to dermatological disorders. But emotional factors *alone* do not account for these disorders. One other factor known to be of considerable importance in the etiology of two of these disorders, urticaria and atopic dermatitis, is allergy, the constitutional or acquired oversensitivity to well defined noxious substances. What evidence exists for the relevance of allergic factors to the etiology of these and kindred disorders? Have these factors been shown to be operative in every case? What evidence has been produced to show the etiological relevance of emotional factors to these disorders? How can the observations of allergists and psychiatrists be reconciled?

Constitutional factors. Both urticaria and atopic dermatitis are frequently connected with exposure to substances, generally proteins, that act as allergens. Often the individual learns by experience which substances must be avoided. Commonly, and particularly in the case of atopic dermatitis, the victim gives a history of past or present allergies involving different systems—a digestive allergy to certain foods in infancy, asthma or hay fever, contact dermatitis, drug reactions, etc. Frequently, a strong family history of allergic responsiveness is elicited.

Various techniques have been developed to demonstrate a responsiveness to allergens when this is suspected. Patch, scratch, and intradermal tests all introduce a dilution of the suspected allergen into the subject's skin. A reactive individual shows a wheal response that contrasts with a control site where a nonallergenic control substance was introduced. More elaborate is the Prausnitz-Küstner method of passive transfer, wherein serum from the patient is injected intradermally into the forearm skin of a nonallergic person, and the area is challenged with the suspected allergen. The presence of reagins is indicated by wheal formation. A simple though unpleasant test of the allergic response is that of exposing the patient to the suspected allergen and seeking to duplicate the eruption. Often dramatically effective, it requires, because of the suggestion factor, that the subject be unaware of the exposure.

Psychological factors. It has been shown by Mitchell, Curran, and Myers that in many patients with allergic disorders an offending allergen cannot

be traced by the usual diagnostic procedures. It is equally clear that a positive skin reaction is not proof of the pathogenic effect of the suspected substances. Allergic investigation of *chronic* urticaria is rarely of value. This is in clear distinction to *acute* urticaria, where allergens are more frequently significant. In atopic dermatitis positive skin tests are frequently present but rarely of therapeutic usefulness. Since evidence of allergy is so often lacking in allergic disorders, it may be inferred that other factors, among them the psychological, play an etiological role.

Many authors have studied the emotional settings of the onset and exacerbations of both atopic dermatitis and chronic urticaria. In these, as in other allergic disorders, there is a strong correlation with emotionally disturbing events that, according to some observers, tend to be somewhat illness-specific and specific in the emotional reaction they induce.

Experimental evidence bears on the interrelationship of psychological and allergic factors. For instance, positive skin test cannot be produced in a previously nonreactive subject, and the extent of an existing allergic skin response can be affected by hypnotic suggestion. Mason and Black hypnotically relieved a patient of her seasonal asthma and hay fever, and her positive skin response disappeared completely. Nonetheless, antibodies continued to be demonstrable by passive transfer.

Ikemi and Nakagawa studied 13 subjects who were highly sensitive to contact with certain specific leaves but insensitive to chestnut leaves. Under hypnosis five subjects were told that they were being touched with chestnut leaves, while actually the allergenic leaves were used. On the other arm, chestnut leaves were applied, with the suggestion that they were the allergenic leaves. Eight subjects were given the same pair of suggestions, blind-folded and without hypnotic induction. All 13 subjects showed a response, in flushing, erythema, or papules, when given the suggestion that the control leaves were allergenic. Four of the five hypnotized and seven of the eight nonhypnotized showed no noticeable response to the allergenic leaves when given the suggestion that they were chestnut leaves. These studies vividly demonstrated the effectiveness of suggestion, with or without a hypnotic induction procedure, in the production and inhibition of an allergic skin response.

An allergic skin reaction can be altered by suggestion or experience that activates significant emotions. Kaneko and Takaishi produced urticarial eruption in known urticarial patients by suggesting under hypnosis feelings of aggression that they could not express. Kalz et al. studied the vascular skin response in patients with atopic dermatitis. The intradermal injection of histamine normally produces a flare response. In some patients it was absent. It was characteristic of the latter group that they restricted the expression or display of emotion. However, after

psychiatric interviews that relieved and discharged previously inhibited aggression, all in this group developed a flare response.

A further large body of experimental evidence is based primarily on research with asthmatics, and on animal studies in which an allergic bronchospastic reaction was developed as a conditioned response.

Personality structure and psychodynamics. The question of the allergic personality has been much debated. Some authors, such as Smith and Marty, have sought to delineate highly specific personality traits; others refer to more general qualities. Many agree that certain features of personality structure and psychodynamics are common to patients with different allergic disorders. The most outstanding is a strong longing for love, a longing of the infantile dependent kind that arises from a sense of deprivation of maternal love in childhood and leads to a passive dependent relationship with the mother and to a fear of estrangement from her and a fear of being left alone. Situations that precipitate allergic attacks are those that reactivate these fears.

As can be seen from the above discussion of atopic dermatitis and urticaria, a wide spectrum of defense mechanisms may be used to deal with these fears, and, accordingly, a wide variety of personalities is found who, on the surface, appear to have little in common.

Psychiatric disorders and allergy. At one time it was felt that alternation of psychosis with allergic disorders was of such frequency as to represent a degree of mutual exclusiveness between the two. More careful investigation, based particularly on asthma, indicates that such mutual exclusiveness is not a frequent occurrence. Nonetheless, there are individual cases in which a clear alternation may be seen. Eng-Kung described a case of urticaria in a Taiwanese woman that repeatedly alternated with episodes of a mixed depressive and paranoid psychosis. In each instance and in line with the theoretical formulation above, the precipitating events for both urticaria and psychosis took the form of rejection and disapproval. Thus, though its frequency may not be great, it may be inferred that for certain individuals psychosis and allergic disorder represent alternative modes of expression of unconscious conflict.

It is, of course, possible that a patient may suffer from a psychological disorder and from an allergic disorder and that the two disorders are not related to each other. Or the same or similar clinical manifestations in different patients may have been brought about by different agents.

But it is also possible that the two types of processes, the allergic process and the psychological process, may be interrelated. Indicative of such an interrelation is the semantic overlap of the words used in both disorders. Both allergic patients and psychiatric patients have in common an oversensitivity to stimuli that are innocuous to others; and in both instances, the oversensitivity, if not inborn, can be

traced back to previous sensitizing experiences. More important, certain psychological features are so commonly found in allergic patients that it is hard to believe that this combination is merely due to chance. More likely, the personality features described are concomitant with an allergic diathesis, and the nature of the response to stressful life situations is determined by the allergic predisposition of the individuals concerned.

Treatment. The therapeutic approach may be from the allergic angle, provided that evidence of existing allergy can be elicited, or from the psychological angle, provided that evidence of emotional maladjustment can be elicited. Each of these measures may have a beneficial desensitizing effect, though it must be borne in mind that removal of a distressing symptom, which can also be obtained by other means, does not resolve emotional conflicts. Psychological disorders arising from them may be more distressing than the psychosomatic disorder from which the patient has been relieved.

Psychotherapy. In practice, it appears advisable to offer psychotherapy to those allergic patients in whom onset and exacerbations of their disorder are clearly related to emotional factors. In patients in whom such factors are not in evidence and in whom test procedures indicate the relevance of allergic factors to the disorder, psychiatric treatment is not indicated.

There are many difficulties in evaluating psychotherapy. These apply equally in the application of psychotherapy to allergy. Nonetheless, the number of sophisticated psychiatric papers appearing in journals relating to allergy suggests that supportive psychotherapy has become increasingly accepted by allergists as an important component in the management of allergic patients.

In general, there has been a high incidence of success and some marked improvement in the published cases. Wittkower treated 21 patients with atopic eczema along analytic lines, and two thirds showed marked improvement. Musaph reported a case of a woman with severe atopic dermatitis and urticaria successfully treated by psychoanalysis. In more recent years, group psychotherapy has been increasingly employed in allergic disease. Groen and Pelsner in a controlled study demonstrated a significant reduction of requirements for symptomatic steroid treatment in the psychiatrically treated group. As might be predicted from the above discussion of the faulty family dynamics, forms of psychotherapy directed at intra-family relationships have proven to be quite successful.

Hypnosis has long been used to intervene in acute allergic episodes, and its application to allergy in general has recently been reviewed by Kroger.

Drugs. A great deal of uncertainty surrounds the use of psychotropic drugs in treatment of allergic disorders. The literature is filled with favorable re-

ports, but most of these have been merely statements of clinical impressions lacking in methodological rigor. A few adequately controlled investigations attest to the usefulness of these drugs.

Lester et al. treated a number of skin disorders, including atopic dermatitis, with psychotropic drugs. They found a positive correlation between dermatological variables and psychological variables, with an over-all dermatological improvement of 50 per cent, as compared with a placebo response of 30 per cent. The basis of the drug selection lay in an understanding of the particular affect state of the patient involved. Thus, when themes of loss, guilt, and depression were most evident, imipramine was the active drug used. In general, the tranquilizers and antidepressants are most effective in the relief of the somatic effects of psychosomatic allergic disorders in that group of cases where the disorder of affect or behavior is most conspicuous. Results have been least gratifying in those cases in which psychopathology appears negligible.

Suggested Cross References

In this section, psychosomatic skin and allergic disorders have been considered from the viewpoint of specificity, according to which specific psychic parameters are related to specific somatic manifestations. For alternate viewpoints on psychophysiological disorders, see Section 29.3 on current concepts of psychosomatic medicine. For a further discussion of the effects of psychological factors in immunological and allergic phenomena, see Stein and Schiavi's section, Section 30.6. Skin disorders of childhood are discussed in Finch's section on psychophysiological disorders of childhood (Section 41.2).

30.11 RHEUMATOID ARTHRITIS

ALFRED O. LUDWIG, M.D.

Introduction

The expressions "a pain in the neck," and "my aching back" must have stemmed originally from an awareness that emotional conflicts may find expression through the musculoskeletal system. At the same time, such disturbances differ from ordinary conversion reactions in three important respects. First, the organs involved in psychophysiological musculoskeletal reactions are innervated primarily by the autonomic nervous system and are not under voluntary control. Second, unlike conversion symptoms, psychophysiological musculoskeletal reactions do not alleviate anxiety. Third, the anxiety symptoms are physiological rather than symbolic in origin, and tissue damage may result.

A diagnosis of psychogenic reaction involving the

musculoskeletal system should not be made simply by the process of excluding organic disease. There should be positive evidence of neurotic conflict. Typically, repressed rage is the emotion which cannot be verbalized or expressed physically and emerges as a physiological disturbance instead. In addition, objective physical signs, such as elevated sedimentation rate, temperature, or leukocytosis should be absent. Unless the symptoms provide marked secondary gain, accurate diagnosis and psychotherapy should suffice to remove them.

Rehabilitation in cases of disability which has resulted from diseases of the muscles or joints may be prolonged when the disability is in the service of a neurotic conflict. In fact, when it cannot be relieved by surgical intervention, even the pain from a diagnosed ruptured intervertebral disc may be a component of a neurotic conflict. Thus, in general, when patients complain of musculoskeletal pain without direct evidence of organic disease, or manifest physical signs and symptoms which cannot be relieved by the administration of minor analgesics, there is usually a significant neurotic component underlying the symptom. In such cases, careful investigation of psychological factors is mandatory. However, it must be emphasized that only properly planned psychotherapy can deal successfully with symptoms which are primarily psychological in origin.

Definition. Rheumatoid arthritis, a disease resulting in marked tissue damage, is a prime example of a psychophysiological disorder. The disease is not localized only in the joints; it may affect many other tissues in the body. Its cause is unknown; at times it appears to be inflammatory, but its infectious origin has not been proven. It tends to be familial. With the exception of cases of spondylitis which are more common in males, there is a higher incidence of rheumatoid arthritis among females.

Clinical Features

The disease may have its onset at any age, from infancy through old age. Constitutional symptoms may be secondary to the joint symptoms but often appear before there are any objective manifestations in the joints. Typically, these include chronic fatigue, loss of appetite, weight loss, vasomotor symptoms, and morning stiffness. The most common precipitating factors appear to be mental and physical strain, or infection. In one controlled study, strain was the precipitating factor in 27.3 per cent of the patients investigated. The disease may begin insidiously, or have a sudden acute onset, and there may be wide variations between these extremes.

Only one or a few joints are affected in some cases, but the joint lesions eventually tend to become symmetrical, and they are accompanied by muscle atrophy. Fever and tachycardia are common. In addition to the joints, many organs of the body may fall prey to the disease: the skin, lymph glands, the

spleen, and the eyes may be affected. Vasomotor symptoms and signs suggest that the central nervous system has been impaired. In addition to fever and tachycardia, a tendency toward autonomic overactivity (including vasomotor instability, increased sweating, diarrhea, and other gastrointestinal disturbances) is common in patients suffering from this disease and often precedes the joint symptoms. In the study referred to above, 67 per cent of the rheumatoid arthritis patients reported such symptoms, in contrast to only 24 per cent of the subjects in the control group. Vasomotor signs were present in 33 per cent of the patients with rheumatoid arthritis, but in only 9 per cent of the patients in the control group.

Psychophysiological Correlations

Psychological factors. A survey of the literature dealing with emotional and personality factors in patients with rheumatoid arthritis, providing data on over 5,000 patients, showed that there is general agreement as to the personality structure of this type of patient. Thus, in comparison with various control groups, patients with rheumatoid arthritis display certain specific psychological characteristics. More precisely, they tend to be masochistic, self-sacrificing, conforming, self-conscious, inhibited, compulsive, overreactive with respect to their illness, and, on quite another level, interested in sports and games.

The investigators surveyed also agreed that emotional factors played an important role in the etiology of the disease and in influencing its course, although there was no consensus regarding the existence of specific precipitating psychic factors. Finally, the literature reviewed emphasized the difficulties in providing adequate control studies, as well as the need for information on the prevalence of rheumatoid arthritis in various populations and ethnic groups and on the racial and geographic distribution of the disease. To acquire such information, international co-operative investigations must be initiated, based on standardized criteria for diagnosis, clinical examination, and the interpretations of roentgenograms and laboratory procedures for the study of rheumatoid arthritis patients.

The results of a detailed study of the psychological factors operative in eight rheumatoid arthritis patients who were referred for both emotional and arthritic complaints were published by Ludwig in 1954. The study was designed to permit careful psychiatric investigation of the patients in the experimental group, in whom the disease had reached various stages of severity. The research design also permitted investigation of the emotional and environmental factors which led to exacerbation or remission of the disease and, in the process, frequently clarified both the conscious and unconscious meaning of these events. The formulations presented below regarding the relationship between psychic and somatic factors in rheu-

matoid arthritis are based on the findings derived from this study.

Somatopsychic correlations. It is important to differentiate the psychological factors, which represent a reaction to the disease process, from those which existed prior to the onset of the disease and may have played a role in its genesis. Every severe illness will have some emotional repercussion, and this is particularly true if the illness is accompanied by physical disability. Rheumatoid arthritis curtails the patient's physical activities, including his ability to work to earn a living, and his social mobility. It may also interfere with his marital and family relationships. In fact, the disability may be so severe that the patient is reduced to a state of helplessness and must remain in bed. Any illness may lead to some regression to passive dependency. But the physical disability characteristic of severe cases of rheumatoid arthritis makes this an even greater danger, insofar as such disability appears to justify the gratification of infantile dependency needs. Accordingly, some of the patients studied used their severe invalidism to demand direct satisfaction of dependency needs, and some became abnormally dependent, despite the fact that their disability was minimal. On the other hand, a third group of patients denied both their disability and, more important, their dependency needs. These patients attempted to deny their wish to be dependent through physical and intellectual overactivity. They also indulged in ingratiating behavior to this end, only to fall prey to masochistic exploitation. Nevertheless, they found it difficult to accept help and resisted all forms of treatment.

Precipitating factors. On the basis of these findings, it may be speculated that these patients might have been able to remain healthy if their dependency needs had been adequately satisfied by their environment or by family or friends. Lindemann has emphasized the importance of object loss as the traumatic event which often precipitates the onset of ulcerative colitis. Similarly, the patients with rheumatoid arthritis reported that the loss of support or separation from a crucial figure had preceded the outbreak of the illness. One patient reacted with repeated depressions and a flare-up of joint symptoms on the anniversaries of the death of close relatives. Of particular interest is the fact that in three of the eight patients studied, object loss was not accompanied by adequate grief reactions.

Ego organization. All the patients studied were profoundly immature and demonstrated weak ego structure. They complained of marked feelings of inadequacy, found it difficult to express their feelings, and often manifested severe anxiety. They all seemed to react to the stress of frustration, rejection, or separation primarily on a somatic level. Since they commonly used denial as a defense, they often displayed a superficial self-confidence and gave the impression of adequate social and work adjustment.

Concomitantly, because of the denial, in many of the cases, the underlying personality defects did not emerge initially, but only after the patient had been observed psychiatrically for some time. Diagnostically, this group of patients might be said to resemble the so-called borderline case. In fact, transient psychotic symptoms were observed in two of the patients in the study group, and in both cases it was apparent that disturbances in ego functioning had preceded the disease.

Disturbances in affect were common phenomena. One such patient was unable to show any emotional response to treatment for over a year. She finally broke down and wept because her husband forgot her birthday, and shortly thereafter she became "furiously angry" for the first time in her life. This episode was followed by complete recovery from all her symptoms, which had included painful swollen joints and constitutional symptoms of excessive fatigue and morning stiffness, together with compulsive overactivity and excessive drinking. A few weeks later, she demonstrated her extreme vulnerability to stress again by overreacting to a mildly critical letter from her mother. On receipt of the letter, she immediately felt tense and anxious, and within 24 hours she experienced sufficient swelling of her midphalangeal joints so that it was impossible for her to remove her rings. However, after she had dealt with these problems in treatment, her symptoms subsided.

Another patient became physically and emotionally rigid and was almost mute during an interview which followed almost immediately an altercation with her mother. Within 24 hours, pain and marked swelling appeared in her knees. And after another 24 hours, when her psychic stress had been alleviated, the attack subsided and her joint symptoms and signs disappeared.

A third patient experienced an almost shocklike reaction to an interpretation from the therapist which she felt implied that her mother rejected her. She became extremely anxious and withdrawn. Her legs and arms became cold, subjectively and objectively. She looked pale and suddenly began to hallucinate. Within a day, joint swelling appeared. Other transient episodes of psychosis occurred while the patient was under psychiatric observation. This same patient also developed a peptic ulcer while the study was in progress.

One of the patients studied was consciously aware of the fact that her symptoms provided a defense against psychotic disorganization. She described episodes in her childhood when she experienced severe panic in response to her mother's sudden attacks of vomiting. She would feel sharp abdominal pain, and then: "I saved myself by being intensely practical ... thinking of some detail, over and over..." Later in life, she substituted compulsive eating and the psychophysiological mechanisms leading to arthritis for the same purpose: "My arthritis, my withholding of material during my interviews, and my obesity are my reality, my security, and my sanity—without them, I cannot live." She was convinced that if she allowed herself to feel, to relax, or to weep, she would disintegrate. The pattern of depression, suicidal ideas, overeating, joint symptoms, and panic was particularly evident during her menstrual periods. On one occasion, when a treatment session was scheduled during a menstrual period, she had a temper tantrum and screamed at the therapist: "I will eat and eat, smash everything to bits, tear you to pieces, and throw your penis in the sewer." Nevertheless, her control of aggression was striking. For example, she harbored murderous impulses toward her mother's favorite dog. She would approach him with serious intent to kill and then lightly stroke his head with complete calm.

Finally, in connection with the disturbances in af-

fect which were typical of patients in the experimental group, the striking similarity in appearance of certain patients who are severely crippled with rheumatoid arthritis and patients with catatonic schizophrenia must be emphasized. Both display rigid, expressionless faces and mutism. When the arthritis reaches this degree of severity, it is possible that it may represent the physiological counterpart of the psychological state of catatonia.

Developmental factors. Patients who were questioned about their early life provided positive confirmation that maternal deprivation had occurred. More specifically, their mothers seemed to have been generally immature, dependent, and unable to provide adequate maternal care.

One young woman remembered feeling strongly rejected when she was sent to stay with her grandmother at the age of 3. She also remembered her mother's punitive training methods quite vividly. For example, her mother had tied her hands to the bed, presumably to control masturbation. This patient manifested both somatic symptoms and psychotic episodes of short duration. When these became inadequate to catheter her intense destructiveness, she occasionally resorted to self-mutilation with razor blades.

Another female patient described her mother as extremely hostile and controlling. She still demanded subservient behavior from her daughter after she had become an adult. The patient recalled that her mother's standards for good behavior required that a child sit quietly on a chair, touch nothing, and cause no difficulty.

A study by Gerard of the mothers of patients suffering from a variety of psychosomatic diseases (ulcerative colitis, celiac disease, megacolon, duodenal ulcer, asthma, obesity, rheumatoid arthritis, and hyperthyroidism) supports the hypothesis that maternal deprivation may be of crucial significance in the onset of these diseases. Gerard emphasized the nature of the early relationships of these children to their mothers, and has described in detail variations in feeding, holding, and supporting the child, as well as the variations in the consistency of these patterns. Gerard concluded that all of these mothers were interested in their children only because they felt narcissistically enhanced by them. They derived little pleasure from the mother-child relationship per se and lacked the capacity for mature motherliness. In fact, most of these mothers were overtly rejecting. Consequently, all of the children had been exposed to frustration of their dependency needs during a period when the gratification of these needs was vitally important.

To illustrate, the mothers of the children with ulcerative colitis instituted punitive methods in very early toilet training. They were very ambitious for the child to achieve training and independence, but, at the same time, they demanded that the child conform. The mother of the child with rheumatoid arthritis was unemotional and perfectionistic. She held her baby stiffly and so firmly that free movement

was inhibited. The child was never caressed. Gerard postulated that severe reactions may occur in response to such severe deprivation in early infancy because of the minimal *Reizschutz*. She believed that the focus of the mother's rejection in particular areas of physiological functioning early in childhood may be the etiological factor in the development of schizophrenia, as opposed to psychosomatic disease, later in life. And, again, the physiological target of rejection may determine specific organ choice in psychosomatic disorder.

Concurrent Disorders

Patients suffering from rheumatoid arthritis may also be subject to other psychophysiological and psychiatric disorders. In four of the eight patients in the experimental group, a positive diagnosis of duodenal ulcer was made in the course of the study. In addition to a duodenal ulcer, one patient developed obesity from compulsive overeating, and, subsequently, severe bronchial asthma. In another patient, alcoholism and barbiturate addiction occurred concurrent with the joint disease.

Psychotic episodes have been reported in patients with rheumatoid arthritis when somatic symptoms and signs were suddenly relieved by means of endocrine therapy. Lindemann reported that the remission of symptoms in one such patient with a moderately severe form of rheumatoid arthritis, involving both peripheral joints and the spine, was followed by a psychosis which lasted for several months. The psychosis, in turn, was completely relieved when the joint symptoms returned.

In the patient described earlier, in whom the somatic expression of emotion served as a defense against psychotic disorganization, the intellectual concentration, focusing, or obsessional thinking was very similar to the phenomenon observed by Pious in a young man with incipient schizophrenia. This patient, too, attempted to maintain contact with reality by obsessional symptoms. Pious also pointed out that his patient had been subjected to severe oral deprivation in childhood, with resulting fixation at the oral-sadistic level of psychosexual development. Intense oral incorporating drives were mobilized for self-preservation, and the hostile rejecting mother figure was introjected and reprojected onto the outside world. Intense passive dependency wishes were activated, along with the unacceptable unconscious goal of reunion in death with her mother.

Simmel has described a specific constellation of symptoms as characteristic of the gastrointestinal stage of development, at which point loving is synonymous with devouring or being devoured. At this level, gratification of the instinct results in the destruction of the object, in contrast to the genital level of psychosexual development, where instinct gratification is accompanied by preservation of the

object. The patient discussed became aware that her compulsive eating was analogous to the compulsive drinking described by Simmel, in that it served to support her defense against depression and against the destructive drives which were directed against herself and others.

There is a conspicuous similarity between some of these defense mechanisms and the primitive mastery techniques observed by Kardiner and Spiegel in patients with traumatic neurosis. Kardiner and Spiegel's patients tended to react to association to the original trauma by spells of unconsciousness or convulsive seizures and sometimes by episodes of wild destructiveness. In this particular patient with rheumatoid arthritis, expressions through somatic channels, with inhibition of the expression of affect or goal-directed motor activity, were substituted for such primitive attempts at oral mastery.

McLaughlin et al. reported some interesting findings in a study of the emotional reactions of rheumatoid arthritis to adrenocorticotrophic hormone (ACTH). In general, the patients in this study were guarded, remote, and unable to express their feelings adequately. They were also characterized as manifesting a marked passive dependence, a high degree of egocentricity, and a lack of genuine interest in other persons. In 10 of the 12 male patients studied, tension was dealt with by the physical activity of hard work or vigorous sport. The 10 women studied also struggled to repress awareness of their hostility and dependence by excessive physical activity. The authors reported the interesting discovery that 6 of the 10 patients who habitually remembered their dreams continued to dream while on ACTH, and these 6 had the best clinical response to ACTH. The patients who could not usually remember any of their dreams continued to repress their dreams while on ACTH and showed a markedly poor response to the drug.

Barchilon's report on a patient with incipient rheumatoid arthritis is particularly relevant to this discussion. Occasionally she became angry and responded to such feelings by engaging in strenuous physical activity. Barchilon believes that these efforts often took place when the patient's joints were hypotonic. Thus, stress and pain were soon followed by muscle soreness and stiffness, and redness and swelling of the joints. He suggests that long periods of hypotonia might have produced some looseness of the joints, with the result that tension might then press together the joint surfaces more strongly and, in the end, result in actual damage. It is conceivable that such a mechanism might precipitate joint trauma or swelling; however, it cannot explain the widespread extra-articular manifestations of rheumatoid arthritis. One can only conclude that a much more complicated and generalized physiological mechanism must be involved.

Physiological Mechanisms

Autonomic activity. It is possible that the physiological changes which occur in rheumatoid arthritis, both in the joints and in other body organs, may be the result of a complicated psychophysiological restitutive mechanism which operates at an archaic physiological (body language) level. In some instances, these mechanisms act as an alternative to psychotic disorganization following object loss. They may serve also to cathartize intense oral destructive impulses. The emotional isolation and other personality defects observed in the series of patients described were present long before the arthritis began. The fact that patients who develop rheumatoid arthritis commonly report that they experienced the symptoms and signs of autonomic overactivity long before the definite onset of the disease suggests at least a partial use of autonomic channels for the dissipation of affect and anxiety. The degree of interference with circulation in many areas of the body following chronic autonomic discharges may be the variable which determines the severity of the illness in individual patients.

Autoimmune mechanisms. A third possible way in which a psychophysiological mechanism may operate to produce rheumatoid arthritis may be through the so-called autoimmune mechanisms. It is generally assumed that in rheumatoid arthritis there is a "rheumatoid factor," which is described as an autoantibody produced against some components of the patients' own tissue. Originally, tissue damage may occur as a result of the circulatory disturbances from the chronic autonomic activity which so often precedes the disease by many years. There is no conclusive evidence to substantiate this view.

In Alexander's view, the organ neuroses cannot be explained as a symbolic channel for expression. Rather, the channel is the autonomic nervous system, and the organ neuroses represent the physiological consequence of emotional tension. He later theorized that there is a universal need for dependency. If the direct outlets for this need are blocked, overactivity of the parasympathetic nervous system results. At the same time, the attempts to restore the original dependency position become more active, and if these are frustrated, sympathetic overactivity results. Finally, Alexander postulated that parasympathetic overactivity might lead to ulcer, diarrhea, colitis, or asthma, while sympathetic overactivity might lead to arthritis, hypertension, migraine, or hyperthyroidism.

The clinical evidence would seem to contradict Alexander's theory, at least in part, for symbolic expressions do seem to influence the location of early joint lesions. For example, not infrequently, the disease may begin in the midphalangeal joint of the ring finger of a newly married woman. In one of our pa-

tients, joint symptoms were often localized on the same side as her mother's hemiplegia.

The similarity in personality traits, the precipitating factors, and the deprivation experienced in the early mother-child relationships of patients with rheumatoid arthritis and those with other psychosomatic disorders, such as peptic ulcer, hypertension, ulcerative colitis, and Raynaud's disease, are more notable than the differences. Certainly, the simultaneous occurrence of several psychosomatic disorders in the same patient observed in a number of cases in our study would seem to point to some common mechanism of origin. Maternal deprivation, as viewed by Gerard, as a common denominator in many psychosomatic disorders, but with variations in the patterns in different disorders, may be an important differentiating feature, and, as such, it warrants further study and corroboration.

Treatment

From the psychological point of view, at certain specific stages in the illness, the therapy of rheumatoid arthritis may reflect the theoretical propositions delineated above. The first phase in the treatment of rheumatoid arthritis, at which point the patient may be extremely ill and perhaps suffering from a high temperature and considerable physical disability, constitutes an acute emergency for the physician. Psychologically, the patient's security has been shattered; physiologically, he has been overwhelmed by his reaction to the precipitating stress. At this stage, the aim is to diminish the intensity of the uncontrolled destructive drives which have been expressed by the onset of the disease before irreversible tissue damage takes place.

This necessitates active supportive therapy which should consist primarily of action rather than words. Ruesch and Bateson have stated that patients suffering from psychosomatic syndrome suffer a constitutional impairment in the development of that part of the nervous system which is concerned with higher symbolic processes. Therefore, verbal interpretations of dynamics will not help, but recovery can be brought about by providing a permissive nursing environment which makes use of preverbal communication. The medical regimen commonly employed during the acute phases of rheumatoid arthritis provides this for the patient. Probing and uncovering of emotionally charged material is contraindicated in this stage.

Striking and rapid improvement not only of joint symptoms, but of accompanying addictive tendencies as well, has been achieved by means of intensive supportive therapy. It is important that attending medical personnel be available to these patients when their anxiety reaches threatening proportions. Those in charge should also be warned against reacting with counter-hostility to the patients' frequently exces-

sive demands, for negativism is often displayed at this stage. Margolin has elaborated these points by proposing what he described as "anaclitic therapy." But it is doubtful whether the average general hospital is equipped to carry out this regimen, which can become extremely disturbing to other patients in the same ward.

When the acute manifestations of the disease have been controlled during the second phase, psychoanalytically oriented psychotherapy can begin. If there is severe regression, orthodox analytic technique may be too frustrating, and a vis-à-vis technique may be more effective. Until a relationship of trust can be established, these patients seem to react primarily to actions and feelings, rather than to words. Contact is easily lost, and the slightest alteration in the relationship between therapist and patient may cause profound reactions. Much time may pass before the therapist is no longer confused with the original hostile mother and can finally emerge as a friendly ally.

As an adjunct to the medical treatment of rheumatoid arthritis, psychotherapy has the best prospects for success if it is employed before there has been extensive tissue damage, marked disability, or secondary gain. In less severe cases, a thorough investigation of possible emotional stress may lead to improvement or removal of at least one important precipitating element.

The internist who treats patients with rheumatoid arthritis must understand that emotional stress may play a very important part both in precipitating the outbreak of the disease and in its subsequent exacerbation. In many instances, he will be able to deal with these aspects himself, as a part of his general medical care of the patient. If there is evidence of more serious definitive psychiatric illness, formal psychiatric investigation and treatment may be necessary.

Suggested Cross References

In this section the psychosomatic aspects of rheumatoid arthritis have been discussed from a psychoanalytic frame of reference. Alternate conceptual approaches to psychophysiological disorders are presented in Section 29.3, on current concepts in psychosomatic medicine.

30.12 PSYCHOGENIC PAIN

FREDERIC T. KAPP, M.D.

Introduction

Human pain is a subjective experience which involves a fusion of mind and body and may form the basis of a variety of psychosomatic syndromes. Pain is first experienced in the life history of the individual as a distinct kind of sensation, a disagreeable feeling which is associated with a specific part of the body. In its simplest form, pain is a somatopsychic phenomenon, a signal that the structural or functional integrity of the body has been impaired, and, as such, it is an important adaptive mechanism. Yet, even this simple process may be complicated by psychic and interpersonal factors. A soldier may not notice his painful wound during the heat of battle when all his attention is focused on the enemy. And women in labor show a wide variation in the amount of pain they experience, depending, among other factors, on their attitudes to motherhood, birth, and their obstetrician.

Psychophysiological mechanisms. Initially, pain develops from various noxious stimuli, arising from the skin, mucous membranes, and internal organs. Thereafter, however, like other sensory phenomena, it may occur without the stimulation of peripheral end organs, in relation to the life experiences of the individual. More specifically, memories of painful experiences which were acquired in childhood may be recalled later, or fantasied, or even hallucinated. In other words, as the human mind acquires the capacity to form symbols by associating concrete experiences with

feelings and ideas, pain is invested with increasingly complex meanings. The etymology of the word "pain," in itself, demonstrates the widespread associations in our culture between the physical sensation of pain and the psychological concepts of suffering, punishment, and repentance.

Psychopathological Determinants

Pain of psychic origin can occur in two forms. It may be a neurotic symptom and represent a symbolic attempt to solve a mental conflict. Or the pain may accompany a psychophysiological disorder which, in itself, is a concomitant of a mental conflict. The underlying conflict in both forms of psychogenic pain may be outside the patient's awareness and involve clashes between dependent, aggressive, or sexual impulses and opposing intrapsychic inhibitions and ideals or external social forces.

Pain as a neurotic symptom. Specific painful experiences in early childhood will determine the individual's perception and response to pain in later life. When the young child experiences physically induced pain, he often associates it with the efforts of crucial persons in his environment to provoke or alleviate such pain. In other words, the perceptive aspects of the pain become fused with emotionally charged life situations. Concomitantly, pain becomes psychologically meaningful and may play a significant role in the adaptive economy of the individual.

In some individuals, for example, such associations may lead to the subsequent use of pain as a way of dealing with life stresses. Such an individual may make a neurotic attempt to solve an overwhelming current conflict by reexperiencing the pain associated with the solution of a similar problem in the past. That is, through the mechanism of conversion, disturbing mental phenomena are withheld from awareness and replaced by bodily phenomena.

Pain is frequently associated with punishment administered in the service of discipline. It is not surprising, then, that this association may be exaggerated in children who are overdisciplined, and made to submit to painful forms of punishment to an excessive degree. As adults, they may be oversensitive to painful sensations originating from physical causes, or they may fantasy or hallucinate pain as a means of self-punishment, in order to abolish or diminish guilty feelings which stem from real or imagined "sins."

Other children, who receive love and attention only when they have a painful injury or disease, are predisposed to another neurotic pain mechanism. Later in life, when these individuals feel the need for more love and care, they may exaggerate a current minor ache or even hallucinate a past pain, in an attempt to regain the sympathy and love they received when they suffered as children.

For some patients, pain is the "currency" which enables them to identify with another person. Here the symptom represents an unconscious imitation of

a pain the other person has or had, or one which the patient wishes the other person would have. Such phenomena are likely to occur in patients who have a hostile-dependent relationship with the person with whom they identify. The painful neurotic symptom keeps the patient from recognizing his aggressive impulses, allows him to express his resentment, and, at the same time, permits a continuation of the relationship.

Finally, for other individuals, pleasure and pain are inextricably intertwined. The equation, set up in childhood, may be used later as a neurotic solution for feelings of guilt in connection with sexual enjoyment. This masochistic type of pain may be experienced along with the pleasure, or it may precede or follow it.

Pain as a symptom in psychophysiological disorders. Many painful syndromes, primarily of emotional origin, are secondary to physiological dysfunctions, which, in turn, are the concomitants of affects such as anxiety, anger, or fear, associated with psychological conflict. This pain differs from the pain which represents a neurotic symptom, described above, in that it is not, in itself, a symbolic expression of mental phenomena. Rather, it represents one aspect of a physiological disturbance associated with an unconscious conflict. The pain results from the stimulation of peripheral end organs, triggered off by the emotionally induced physiological dysfunction. In addition, the peripherally induced pain is often exaggerated by the emotionally disturbed patient.

The pain accompanying psychophysiological disorders may involve many organ systems. Common examples include tension headaches, and some cases of "fibrositis" and low back pain secondary to striated muscle tension; migraine secondary to vascular dysfunction; and cardiospasm and spastic colon secondary to smooth muscle hypertonicity.

Clinical Features

Pain of psychogenic origin is not symptomatic of a specific type of psychological illness. However, it commonly occurs as a prominent symptom in conversion reactions and is frequently encountered in both psychoneurotic and psychotic depressive reactions. In some cases of depression, pain masks or replaces the affective symptoms; in other instances, it occurs concurrently. Pain is frequently part of the clinical picture in anxiety reactions and hypochondriacal syndromes, both neurotic and psychotic. Certain individuals have a life-long proclivity for chronic pain and have been appropriately termed "pain-prone" by Engel. Emotional factors may play a decisive role in the genesis of pain in a number of chronic intractable pain syndromes, such as painful phantom limb, minor causalgia, atypical facial neuralgia, and painful post-traumatic states.

Differential diagnosis. The diagnosis of pain which does not arise from obvious physical causes requires

skill and thoroughness in evaluating the neurological, psychic, and social aspects of the problem. Frequently, psychogenic pain is associated with localized tenderness, changes in autonomic function, functional motor weakness, and hyperalgesia. The pain and its associated phenomena are localized on the basis of the patient's body image, rather than his neuroanatomical constitution. It is often flamboyantly described by the patient in meaningful metaphors or similes: "It's tearing me apart," or "It cuts me like a knife." A description of short-acting, sharp pain suggests the possible presence of a local lesion. A description of long-acting or chronic pain, diffuse in character, suggests that, in some cases, the pain may be primarily psychic in origin.

This history of the patient with psychogenic pain may reveal that he feels threatened or injured because of inner conflicts, or because of distortions in his relationships with persons to whom he has strong emotional ties. A connection can often be established between the site of the pain, some previous painful experience associated with a psychological trauma, and a similar difficult current life situation. A history of obvious conversion symptoms or of depressive illness may provide valuable clues. Finally, a history of frequent previous surgical operations for recurring abdominal pain of obscure origin is often a valid diagnostic criterion in such cases.

Management

Patients whose major symptom is psychogenic pain often present difficult management problems for the physician. If treatment is to be effective, the doctor must encourage the patient to talk freely about his psychological, as well as his physical problems, so that he can gain an understanding of the patient's symptom. He must learn about the patient's personality make-up and life adjustments prior to the development of the painful syndrome, and particularly the psychological setting in which the pain was first experienced.

The doctor-patient relationship is of particular significance, for the symptom may be used in the service of this relationship. For example, pain may be presented as the chief complaint because the patient believes, sometimes correctly, that the doctor will be more sympathetic and helpful if the illness is "physical," than if he were to reveal his underlying emotional problem. The pain then becomes an expression of suffering and an appeal for help.

Treatment may be symptomatic or specific, depending on the potential strengths of the patient to deal with his emotional problems in a healthy manner, the severity and duration of the disability, and the skills of the physician. Relationship psychotherapy alone, or sometimes in combination with drugs or hypnosis, is helpful in some cases. Insight psychotherapy is indicated for patients who are willing and able to deal with their emotional problems. However,

patients who are unable or unwilling to face their problems are likely to become depressed or develop another, even more disabling symptom if their pain is removed; the physician can best treat these patients by helping them to learn to live with their pain.

A wide range of symptomatic therapeutic procedures has been advocated for the relief of these painful syndromes. These include the usual analgesic drugs and a variety of procedures, ranging from injections of anesthetics into the skin and peripheral nerves, to sympathectomy, lobotomy, or ablation of local areas of the sensory cortex. Narcotics are to be avoided because of the danger of addiction. However, the phenothiazines are of value, especially when the patient's primary disorder is a psychotic one; and antidepressant drugs and electroconvulsive therapy may be useful if the pain is a manifestation of a depressive syndrome. But even when he administers symptomatic treatment, the physician must deal with the personality structure and current life situation of his patient and understand the manifold psychological implications of his pain.

fact, throughout the world, only cancer and cardiovascular diseases outrank accidents as a cause of death. Furthermore, while spectacular progress has been made in the control of many diseases, the annual fatality rate for accidents remains virtually what it was in 1900—about 88 persons per 100,000 population. It is not surprising, under the circumstances, that fields relating to medicine are characterized by less dependable information and a greater prevalence of misconceptions, even among professionals.

Definitions. Even the definitions of accident and accident proneness are subject to widespread misunderstanding. An accident is commonly defined as an event which happens by chance or unexpectedly and, in particular, one which, in Webster's words, is "of an afflictive or unfortunate nature." In a sense, when a pedestrian is struck by a speeding car while crossing the street, or a child falls from a jungle gym and breaks his leg, these events usually do occur "unexpectedly," that is, without conscious foresight or expectation. In other words, these accidents usually are "accidental." On the other hand, however, while such events may be unexpected, they are seldom simply the result of "chance"—of the perverse whims of an unpredictable, uncontrollable fate. Chance implies the absence of cause; current research suggests not only that accidents do have causes, but that it is possible to determine the specific nature of these causes in many instances.

Differential diagnosis. The very term "accident proneness" implies the existence of causal factors, specifically, that an individual's accident pattern is the result of certain enduring psychological, psychophysiological, or physical defects which predispose him to accidents. Yet here, again, misunderstandings arise. The diagnosis of accident proneness is frequently based simply upon a record of repeated accidents. However, a high incidence of accidents does not, in itself, justify such a diagnosis. It is perfectly possible for a person who does not deviate significantly from the norm in his basic psychophysiological functioning to have a higher than average accident rate. Even unloaded dice occasionally turn up with a "seven" many times in a row.

Admittedly, such instances are rare; consequently, when they occur, one is well advised to look further for factors which may be significantly related to their occurrence. But even when such factors can be identified, they may not turn out to be primarily organismic in nature. For example, one individual may have more motor vehicle accidents than another simply because his job requires him to drive many thousands more miles per year; in accident research terminology, his higher accident rate might then be primarily a function of increased "exposure." Similarly, one child may have many more accidents than another principally because he lives and plays in a higher risk environment, physically and socially. The physician cannot exclude the possible role of occupational

30.13 ACCIDENT PRONENESS

JOHN J. CONGER, Ph.D.

HERBERT S. GASKILL, M.D.

Introduction

Accidents constitute one of the most significant health hazards of our time. In this country, they are the leading cause of death among that segment of the population between the ages of 1 and 36. And, in

and environmental factors from diagnostic consideration in his approach to the problem of accident proneness.

Nevertheless, despite the validity of such factors, both formal, controlled research and clinical observation indicate that the personal characteristics of an individual play an important part—possibly the most important part—in accident repetition. And, in this sense, the term “accident proneness” may have considerable clinical justification. It should be emphasized, however, that the diagnosis, when made, should be based not simply on accident frequency or severity, but on the elucidation of those specific psychological, psychophysiological, and physical characteristics which distinguish the individual accident repeater from persons with low accident rates. Hopefully, the diagnosis will also be based, to some degree, on an understanding of the underlying mechanisms through which these characteristics affect the individual's increased accident susceptibility.

Characteristics which distinguish accident-susceptible individuals from those who are relatively accident-free are described below.

Accidents Involving Adults

Psychological factors. Most of the more carefully controlled studies of the role of psychological factors in accident susceptibility have involved motor vehicle accidents; hence, caution must be exercised to avoid overgeneralization. Nevertheless, it seems reasonable to postulate that similar psychological factors are involved in other kinds of accidents, although some, such as childhood accidents, probably also present significant differences.

In one carefully controlled study of motor vehicle accidents, subjects with higher accident rates showed the following statistically significant tendencies. (1) These subjects had less of a capacity for masking or controlling hostility than the accident-free subjects. (2) They were either excessively self-centered and indifferent to the rights of others, or excessively socially centered; i.e., they manifested an “over-determined” awareness of, interest in, and respect for the rights and feelings of others. (3) They were either excessively preoccupied with fantasy, or extremely “stimulus-bound.” (4) They were more fearful of loss of love and support than the other group (and, by inference, more angry and resentful toward persons viewed as depriving). (5) In general, individuals with higher accident rates were less able to tolerate tension than were the controls. In addition, these subjects were categorized as consistently or occasionally belligerent or covertly hostile more frequently, and as appropriately assertive or unassertive less frequently. In contrast, on the whole, the accident-free subjects were rated as more conventional and better adjusted.

On the other hand, no differences were noted between the accident-prone group and the accident-free group with regard to the following parameters:

reality orientation, castration anxiety, friendship patterns, hostile impulses (without reference to capacity for control), and clinical diagnosis of character type.

In a recent, still unpublished study of 15-year olds (Conger and Miller), it was found that students who later had automobile accidents were rated more unfavorably by teachers than their accident-free peers on a number of characteristics. Accident subjects were rated as having poorer attitudes toward authority, less respect and consideration for the rights of others, poorer work habits, less involvement in meeting group responsibilities, less social and emotional stability, and less sound social values.

Other investigations of motor vehicle accidents have reported a higher incidence of such characteristics as emotional instability, impulsiveness, lack of alertness, egocentricity, irritability, foolhardiness, inadequacy, and poor social and vocational adjustment among drivers with high accident rates, in contrast to those drivers who had not been involved in accidents. And, finally, a number of clinical reports on accident-susceptible patients, based primarily on psychoanalytic observations, have stressed the significance of such precipitating factors as (1) inadequate or incomplete repression of hostile impulses; (2) “unconscious needs for punishment, for sacrifice, or for making restitution for some previous act or wish”; (3) highly specific aspects of the individual-environment interaction (e.g., a woman driver patient with strongly repressed sexual desires had been involved in an accident in which a man “banged into [her] tail”). While the fact that unconscious motives play a dominant role in some accidents cannot be disputed, there is no apparent justification for Brenner's assumption that “insofar as a foreseeable mishap is caused by a ‘human imperfection’ in the performance of some action or other... it was unconsciously intended by the performer of that action.”

Psychophysiological and psychophysical factors. Evidence available to date suggests that the popular concept of the role of physical and psychophysical factors in accident susceptibility may have been exaggerated. In one study of relatively healthy young males, it was found that the traditional measures which are often assumed to represent the crucial difference between safe and unsafe drivers—e.g., reaction time, depth perception, and eye-hand coordination, as well as intelligence—seem to make little difference in most cases.

In this same study, scores were obtained for measures of respiration, muscle tension, psychogalvanic skin reflex, heart rate, and a combined measure of over-all reactivity under rest and stress conditions. There were wide differences in the scores of individual subjects; but none of the measures discriminated between accident and accident-free subjects, although there was some tendency for the accident group to have a slightly faster heart rate. At the same time, however, it should be emphasized that these results

are not intended to indicate that people are not more susceptible to accidents under conditions of psychophysiological stress. On the contrary, a variety of studies indicate that people are more susceptible to accidents (1) when they have been drinking (at least half of all fatal motor vehicle accidents appear to have involved a drinking driver, and, not infrequently, an alcoholic); (2) when they have been taking tranquilizers or sedative drugs; (3) when they are suffering from extreme fatigue. The author of a recent, particularly interesting study determined the point in the menstrual cycle at which 84 regularly menstruating women were involved in various kinds of accidents (Dalton). Her findings showed that more than half of all accidents involving this group of subjects occurred during menstruation or in the four days preceding menstruation (see Figure 1).

Accidents in Childhood

As noted above, children's accidents probably differ in a number of important ways from the accidents of adults. The adult, because of his greater knowledge and experience and his more advanced mental and physical development, is potentially better able than the young child to notice, evaluate, and respond appropriately to risk situations. In brief, basically, the adult is more capable of anticipating and avoiding accidents, and whether or not he does so will depend primarily on special psychological factors. The child's accident rate, on the other hand, may be a function of the safety practices and teachings of his parents to a significant degree and, as such, will depend on the number of potential accident situations to which he is exposed.

Psychological factors. It also appears, however, that some children are more susceptible psychologically to accidents than others, regardless of the state of their knowledge of, or experience with, potential accident situations. Preliminary evidence suggests that children with high accident rates tend to be more than normally anxious, more disturbed emotionally, and more active (both before and after birth), and to show earlier motor development and better coordination. In addition, the parents of such children are more likely to be anxious, insecure, unassertive, and less involved in parent-child interactions.

Accident Proneness versus Accident Susceptibility

It was pointed out earlier in this section that the term "accident proneness" implies that an individual has enduring personal characteristics which predispose him to accidents; on the other hand, the "normal" individual's accident susceptibility will depend on his psychophysiological state at a given moment. Most accidents are accounted for by the "average" person, rather than the habitual accident repeater. And clinical evidence suggests that temporary psychological

FIGURE 1. Distribution of 84 accidents in the menstrual cycle. (From Dalton, K. Menstruation and accidents. *Brit. Med. J.*, 2: 1425, 1960.)

and psychophysiological stress may constitute a significant causal factor in such accidents.

Dynamics of accident susceptibility. The ability to avoid accidents depends on a number of complex psychological and psychophysiological processes: the individual must maintain an attitude of constant alertness to the external world; an ability to evaluate possible risk situations, together with the capacity to act quickly and intelligently to avoid them; and, finally, the *wish*, conscious or unconscious, to avoid such situations. Anything that interferes with any of these processes, even temporarily, will increase the individual's accident susceptibility. Thus, as mentioned above, such physiological influences as fatigue, illness, alcohol, and sedative drugs may impair a person's efficiency and consequently increase the likelihood of his having an accident.

Emotional influences may have a similar effect. Whenever a person is temporarily tense and angry, unusually elated, or preoccupied with worries, his alertness to potential risk situations and his capacity to deal with them effectively are impaired. Furthermore, clinical observation indicates that he may even fail to care about danger, and, in some instances, he may actually court danger, either consciously or unconsciously.

Management

There are few reports in the literature on the management of patients who are highly susceptible to accidents or on the degree of therapeutic success achieved in such cases. Obviously, psychotherapy is indicated where chronic, unconscious motivational factors appear to be involved. However, the psychiatrist must remember that accident susceptibility may also depend on transient social, emotional, and psychophysiological stresses. And, in some cases, accident susceptibility may be attributed primarily to "educational" factors, such as the patient's lack of sufficient awareness of risk, inappropriate responses in risk situations, and failure to develop habits of minimizing risk. Such additional factors must be taken

into account in any attempt at comprehensive management.

Finally, it should be remembered that simply participating actively in today's complex, rapidly changing world involves risk. In fact, preliminary evidence suggests that persons who are unusually accident-free often have chronic emotional problems, although they differ from the problems of subjects with high accident rates.

30.14 HEADACHE

ARNOLD P. FRIEDMAN, M.D.

Introduction

One of the most difficult (and often frustrating) problems in medical practice is the treatment of the patient who complains of chronic recurring headache. Since headache is a symptom and not a disease, the meaning of headache can only be considered in relation to the patient and the complete setting in which his complaints occur. However, in the most common headache syndromes, i.e., the vascular types and muscle contraction headaches, no structural changes are evident between attacks, and there is close relationship between the occurrence of headache and anxiety-

producing situations. Psychological factors may be involved in a variety of ways: (1) directly, by precipitating changes in specific physiological function, i.e., cranial vascular changes, sustained muscle contraction, and the increased or decreased activity of various glands; (2) as conversion phenomena, i.e., conversion of an emotional conflict into a physical dysfunction; and (3) as a result of delusional or hypochondriacal states.

Nevertheless, in all patients, a number of organic processes which may simulate these common types of headache must be ruled out before a definite diagnosis can be established. In brief, it is mandatory that every patient with chronic headache be thoroughly evaluated by medical and neurological examination, ancillary tests, and a careful personality appraisal.

Psychological determinants. Many psychological adaptive factors may play a part in determining the symptom choice of head pain. Among them are the positive or negative "identification" with a family figure, and the introjection of that figure. Identification may also play a role in other cases, where symptoms arise from the patient's desire to gain attention or affection. In some patients, the headache may arise as a result of their need to remain dependent.

The chronic headache symptom may occur in persons who previously suffered a head injury or illness in which head pain was a prominent component. The memory of such past experiences is activated when the patient encounters similar experiences or situations, particularly when the patient's pattern of psychological functioning is one in which pain is utilized to alleviate feelings of hostility associated with guilt.

Clinically, the conflicts observed most frequently in headache patients involve hostile and aggressive impulses of an intense and destructive nature. Typically, the headache develops when the patient reaches the limit of his capacity to tolerate his repressed or suppressed anger. In addition, this hostility arises from and gives rise to feelings of guilt which are usually unconscious and which, in themselves, may be responsible for the pain, in which case the punishment (physical pain and suffering) is self-inflicted.

Classification of Headache

A classification of headache by mechanism recently published in the *Journal of the American Medical Association* provides a useful framework for the presentation of pertinent information with regard to diagnosis and treatment. Fifteen types of headache are cited: (1) vascular headache of migraine type: a. classic migraine; b. common migraine; c. cluster headache; d. hemiplegic and ophthalmoplegic migraine; e. lower-half headache; (2) muscle contraction headache; (3) combined headache (vascular and muscle contraction); (4) headache of nasal vasomotor reaction; (5) headache of delusional, conversion, or hypochondriacal states; (6) nonmigrainous vascular headache;

(7) traction headache; (8) headache due to overt cranial inflammation; (9-13) headache due to disease of ocular, aural, nasal and sinus, dental, or other cranial or neck structures; (14) cranial neuritis; and (15) cranial neuralgias.

Vascular headache of migraine type

Clinical features. The essential nature of migraine still remains unclear, but it is unquestionably a complex biological reaction which in some cases is closely related to stressful attitudes and frustrating life situations.

Essentially, the diagnosis of migraine is made on the basis of the patient's history and on the absence of evidence of intracranial pathology. Such headaches occur in recurrent attacks, are commonly unilateral in onset, and are usually associated with anorexia, sometimes nausea and vomiting, or systemic disturbance. In some instances, the migraine attack is preceded by, or associated with, conspicuous sensory, motor, and mood disturbances. Migraine headaches often occur in members of the same family.

Some of the migraine variants exhibit specific phenomena. In classic migraine, the headache is preceded by sharply defined, transient, visual or other sensory disturbance or motor prodromes, or both. Cluster headaches (histaminic cephalgia, migrainous neuralgia) occur in clusters of short duration. In an occasional patient, an ophthalmoplegia or hemiplegia may appear late in the course of a headache attack. The process is usually completely reversible, and the precise mechanism is unknown. Migraine complicated by persistent ophthalmoplegia, facial paresis, hemiplegia, or visual field defects is more difficult to diagnose. Only rarely is a demonstrable intracranial lesion, such as a vascular anomaly, found eventually.

Physiological mechanisms. In all vascular migraine headaches, arterial dilation and a periarterial tissue reaction occur concomitantly. Often, one major artery of the carotid tree becomes dilated; in some cases, the involved artery may constrict before it dilates. The exact mechanism of the arterial dilation and the periarterial tissue reaction is unknown, although the available evidence suggests that the dilation is neurogenic and that the periarterial response is mediated by an accumulation of tissue substances which can induce dilation of small vessels, edema, and tenderness. Undoubtedly, the cerebral cortex and vasomotor centers are involved in initiating the onset of the migrainous attack, but, once again, the specific central pathways are unknown.

Psychological factors. For many years the migraine patient was thought to be relatively free of psychological disturbance between headache episodes. It is now recognized, however, that the personality structure of the migrainoid predisposes him to chronicity. Specifically, most migraine patients were not permitted to express emotions of anger and rage as

children; rather, they learned that love and approval were to be gained only by emotional suppression. Accordingly, they set up mechanisms to control their natural behavior; that is, they rechanneled their hostilities into ambition and striving for success and, in the process, created a way of life which imposed excessive environmental demands. This psychological background, added to a sensitive autonomic nervous system, causes them to over-respond to these demands. Thus, they suffer situational anxieties, as well as those caused by deeper, unconscious conflicts.

Most migraine patients are bright and knowledgeable, with highly developed intellectual techniques for dealing with their life crises. They are overcontrolled and function in a sustained state of emotional restraint, reacting to stress with anxiety. Their personality structure is characterized by perfectionism, neatness, ambition, rigidity, and efficiency. Prolonged stimuli, such as puberty, menstruation, maturation, leaving home, seeking work, and meeting the responsibilities of a job, marriage, or parenthood, can trigger a migraine attack.

However, migraine and other forms of chronic headache may also mask a more serious psychological disturbance. For example, the release of hostility by a migrainoid obsessional patient often causes depression which must be differentiated from the more common types of depression.

Differential diagnosis. It is imperative that the physician be alert to the fact that headaches caused by other conditions sometimes simulate migraine, including aneurysms, vascular malformations, and other expanding intracranial lesions.

In older patients, a late onset of headaches resembling common migraine, with sensory and motor symptoms, may indicate basilar or carotid artery insufficiency. Glaucoma or temporal arteritis must also be considered in these older patients. Polycythemia, anxiety, hypersensitivity (allergy) reactions, depression, and hypertension can also masquerade as migraine and should be considered in differential diagnosis.

Muscle contraction headache

Clinical features. The patient complains of periodic, recurring headaches, which vary in frequency and severity and usually persist for hours or even days. The onset of the headache is often directly related to a specific stress situation. The pain is usually bilateral and suboccipital, although it may also be referred to the frontal region, i.e., the face (causing spasm of the masseter muscles), or be felt around the entire head like a band. Examination at the time of headache reveals excessive muscle contraction; frequently, the patient also complains of tenderness in the neck and sometimes in the scalp. Presumably, tension and emotional stress cause the tightening of the neck and scalp muscles and the prolonged muscle contraction. Ischemia has also been suggested as a contributing factor in the pain and excessive muscle contraction.

Psychological factors. These patients are in a state of chronic anxiety: they are usually tense, apprehensive, sensitive to the opinions of others, easily embarrassed, and worried. Careful history taking uncovers sleep problems, feelings of irritability and restlessness, various psychosomatic disturbances, occasional outbursts of aggression, and fits of weeping. Sometimes the patient mentions his fears of going insane. This, too, is a manifestation of chronic anxiety, which is caused by forbidden, hostile, or aggressive feelings, and unacceptable sexual strivings which threaten to break through the repressing influence of a conscience or the superego. The patient seeks to avoid public exposure of his weakness, by demonstrating the classic symptoms of anxiety; therefore, he stiffens his neck so that his head will not tremble when he feels anxious.

Differential diagnosis. A diagnosis of muscle contraction headache should not be made purely on the basis of the patient's description of the distribution and character of the pain. The possibility of other causes must always be considered: intracranial lesions, intraspinal tumors, cervical spondylosis, fibrositis, hypertension, cervical discogenic disease, and even migraine. All of these may be accompanied by a muscle contraction headache as a secondary reaction. Again, the patient may have migraine headache at one time and muscle contraction headache at another time. In fact, this phenomenon is frequently encountered as a somatic expression of a chronic anxiety in association with the obsessive component in compulsive-depressive reactions.

Headache of nasal vasomotor reaction (vasomotor rhinitis)

Clinical features. In some cases, headache may be associated with bilateral nasal discomfort; these patients often refer to their headache as a "sinus headache." When allergens, infectious agents, or gross anatomic deformities are not demonstrably implicated, the disorder may be diagnosed as vasomotor rhinitis. The patient may complain of nasal obstruction, tight sensations, burning, or rhinorrhea. The nasal mucous membranes may look engorged and edematous. However, chronic sinusitis is not a common cause of headache. Typically, sinus headache is localized in one region, is periodic in character, and is accompanied by localized tenderness, and x-ray evidence of sinusitis is usually present. Vague headache and discomfort without demonstration of definite sinusitis calls for a thorough psychosomatic study of the patient.

Treatment

The treatment of chronic headache encompasses a wide range of therapeutic approaches. In the more common headache syndromes, treatment is focused on the termination or prevention of the headache attack. When headache pain is initiated by a pathologi-

cal process, treatment is aimed at extirpating or ameliorating the pathological process, rather than on the headache symptom. In any event, whatever the cause of the headache, the whole patient must be considered: every patient who suffers severe chronic pain requires psychological support. Moreover, in the vascular and muscle contraction headaches, psychotherapy is the treatment of choice, although pharmacotherapy has its place. A discussion of the psychiatric techniques employed in the treatment of chronic headache lies beyond the scope of this section and is presented elsewhere in this volume.

Pharmacological management

Migraine headache. The pharmacological management of migraine headache is best accomplished by ergotamine tartrate combined with caffeine. When nausea and vomiting occur during the migraine attack, ergotamine may be combined with other drugs (antiemetics, antispasmodics, or sedatives). A number of proprietary preparations of such combinations are available.

As a general rule, the following program of ergotamine therapy has proven most effective. From 2 to 4 mg. of ergotamine are administered orally or sublingually, at the onset of the headache, followed by 2 mg. every hour until the headache has disappeared, or until the patient has taken 10 mg. of the drug. (This limit should not be exceeded.) When the drug is taken rectally, 2 to 4 mg. should be administered at onset, followed by 2 mg. every hour until the headache has disappeared, or until 8 mg. have been taken. Intramuscularly, 0.25 to 0.30 mg. of the drug should be administered at onset. In rare instances, ergotamine may be given intravenously, but in such cases the drug should not be given more often than once in 10 days.

On the whole, the prevention of migraine attack by chemical agents has been unsuccessful to date, but a drug introduced recently, methysergide maleate, has proven an effective prophylactic agent in a considerable number of patients. The drug is administered orally at mealtime or with food in 2-mg. tablets, with an average daily dosage of 6 mg. Patients on methysergide therapy should be seen at frequent intervals so that their dosage level may be adjusted and any side effects evaluated. A few patients have demonstrated serious side effects, such as vasospastic manifestations, psychic reactions, retroperitoneal fibrosis, and cardiac changes. However, the cause and effect relation of the drug to these disorders has not been clearly established.

Muscle contraction headache. Symptomatic relief from muscle contraction headache may be obtained with the use of non-narcotic analgesics, such as the salicylates, combined with caffeine and a mild sedative. Innumerable preparations of this sort are available and are well known to all physicians. It should be noted, however, that muscle contraction headache is

chronic, and many of the patients are great pill swallowers. Therefore, combinations which contain sedatives and narcotics should be prescribed with caution. Tranquilizers may reduce the patient's emotional reaction to stress, but they are of limited value. Prevention by muscle relaxants has not proved convincing.

Finally, it must be emphasized, once again, that the most effective prescription in chronic headache syndromes is dynamic psychotherapy, which allows recognition of conflict and modification of the underlying pathological personality structure.

this patient population is similar to the treatment of patients whose symptomatology is confined to disturbances of behavior. Thus all of the therapeutic techniques available to psychiatry may be employed appropriately in the management of psychosomatic patients.

There are, however, some special considerations concerning treatment which must be taken into account in the management of psychosomatic patients. These considerations derive from the unique relationship between such patients' psychic experiences and their somatic reactions.

The combined medical and psychiatric treatment of psychosomatic disorders. Psychophysiological disorders involve diseased organs which are vulnerable to the physiological concomitants of emotional arousal. Therefore, treatment must be aimed at both the physical and the emotional aspects of the disease. Often, the management of the psychosomatic patient is the sole responsibility of the internist. Although he will concentrate on the treatment of his patient's somatic symptoms, his efforts will also be guided by careful consideration of psychological factors. Less frequently, the psychiatrist has the sole responsibility for the management of the psychosomatic patient, in which event he must remain alert to exacerbation of the patient's physical symptoms throughout the course of treatment. However, many patients in this diagnostic category require the combined skills of several specialists. Thus, patients with serious organic pathology require the regular services of a surgical or medical specialist, and, in addition, by virtue of his special skills, the psychiatrist's intervention is indicated in those cases where complex psychopathology is considered to constitute a crucial determinant of the illness. The concurrent treatment of psychosomatic disorders by a medical or surgical specialist and a psychiatrist is referred to as combined treatment.

In psychosomatic disorders, psychic and physiological processes are intimately interwoven: the patient's psychic state exerts a continuous and significant influence on the physiological symptoms which are the target of the medical treatment. Consequently, the psychiatric and medical aspects of the treatment process, whether implemented by one or two specialists, should be closely integrated. From time to time, during changes in the clinical course of the psychophysiological disorder, there may be a relative shift in emphasis from one form of treatment to the other. However, both the somatic and the psychic status must remain in proper perspective at all times. For no matter how skillfully planned and executed, medical treatment of an afflicted end organ may fail to achieve its goal unless the treatment regimen also reflects an awareness of the patient's emotional state. To illustrate, medical treatment of acutely bleeding duodenal ulcer by such means as appropriate hemostasis as well as antacids, anticholinergic, and demul-

30.15 TREATMENT OF PSYCHOPHYSIOLOGICAL DISORDERS

HELEN S. KAPLAN, M.D., Ph.D.

Introduction

Patients with psychophysiological disorders represent a wide spectrum of psychiatric diagnoses and manifest the entire gamut of possible psychological problems. Consequently, the psychiatric treatment of

cent medication has proven highly effective. Nevertheless, this medical regimen may fail to result in healing of the duodenal lesion if the patient is depressed, agitated, guilt-ridden, or acutely psychotic. Such psychic states may have profound physiological effects on the patient's gastrointestinal tract which may interfere with healing and will also affect the action of the medication. For example, 1.5 mg. of Pro-Banthine (propantheline bromide) may effectively reduce the secretion of hydrochloric acid when acting on the quiescent, pale gastric mucosa of a calm patient. However, the same dose of the same medication may be ineffective when acting on an angry patient's hyperactive, red mucosa which is pouring out secretions.

Thus, psychiatric therapy which is aimed at amelioration of the patient's psychopathological state can act synergistically with the medical treatment to facilitate healing of the somatic lesion. On the other hand, medical and surgical treatment also facilitates the psychiatric treatment of psychophysiological disorders. Specifically, the vulnerability of the diseased organ to the effects of emotional arousal is a limiting factor in psychiatric intervention. Thus, medical and surgical treatment, by increasing the patient's physical resistance, permits the psychiatrist greater therapeutic flexibility.

During the acute and physically dangerous phases which are characteristic of some of the psychophysiological disorders, medical treatment inevitably assumes relatively greater importance, although, even in the acute stage of illness management of the patient's emotional state should not be neglected. During the chronic stages, when the illness is in remission, psychiatric treatment, although it is still combined with medical management, generally assumes greater importance. Some clinicians feel that when psychiatric treatment is administered during the chronic stages of psychosomatic illness, it helps to prevent recurrences of acute episodes; it may also help to limit the extension of an existing disease by modifying the underlying psychopathology.

While therapeutic intervention in psychosomatic disease is aimed at both somatic and psychic components, the following discussion will be confined to a consideration of the psychiatric treatment of psychosomatic disorders.

Psychiatric Treatment of Psychosomatic Disorders

Fundamental assumptions. The inclusion of psychiatric treatment as part of the therapeutic regimen in psychosomatic disorders is justified by the basic assumption that psychic factors are important determinants of such disorders. More specifically, psychosomatic disorders are believed to be multicausal in origin: they are the result of the complex interaction of a variety of somatic and psychic factors. Treatment is directed at all accessible symptoms and determinants, including the crucial psychic factors which are often accessible to change through psychiatric inter-

vention. Psychiatric treatment of psychosomatic disorders is based on another basic assumption concerning the mechanism by which psychic factors contribute to psychophysiological disorders. Presumably, the physiological concomitants of emotional arousal constitute the pathogenic intervening variable in the psychic process. Under normal circumstances, the human body can tolerate the physiological upheavals which accompany emotional arousal without undue ill effect. However, if emotional reactions are excessively prolonged or severe or assume a pathological pattern, and if a particular organ is unusually vulnerable to physiological effects of emotion, then psychophysiological symptoms and disease may result. The psychiatric treatment of psychophysiological disorders is based on this conceptual model.

Psychiatric treatment cannot alter basic organ vulnerability, but it can diminish the stress to which the organ is subjected. The goal of psychiatric intervention is to diminish or alter the patient's pathogenic emotional reactions, especially anxiety, in the hope that this will produce a concomitant amelioration in his somatic symptoms. Beyond these general principles, since, as mentioned above, patients who suffer from psychosomatic disorders typically manifest a broad spectrum of psychiatric problems, there is no universal rule with regard to therapy. The psychiatrist's choice of technique used to reduce the anxiety will depend on the specific problems presented by each individual patient.

Variables in the treatment of psychosomatic disorders. In planning a treatment regimen for a patient who suffers from a psychiatric disorder which is limited to behavioral symptoms, such complex psychic factors as the patient's psychiatric diagnosis, behavioral symptoms, psychodynamic organization, adaptive resources, emotional assets and liabilities, as well as the potential assets and stresses of his environment, must be taken into consideration. Planning the treatment regimen for patients with psychosomatic disorders is even more complicated, because in addition to all these psychiatric considerations, complex somatic as well as psychophysiological factors must also be accounted for.

Somatic factors in the treatment of psychosomatic disorders. The somatic factors which are particularly significant in the psychiatric treatment of psychosomatic disorders are (1) the medical aspects of the disorder; and (2) the psychophysiological effects of the psychiatric methods employed in the treatment.

Medical status. The nature and severity of the patient's medical illness, as well as the anticipated effects of emotional arousal on the afflicted organ, the nature of the medical treatment he is receiving, possible future complications, and his dependence on his medical regimen, constitute important data for the psychiatrist because the conduct of therapy and the therapeutic goals are influenced thereby.

As might be expected, the prognosis is also affected by the patient's medical status. In general, the likelihood of obtaining successful results varies with the chronicity of the patient's psychosomatic conditions. The best results are achieved in cases of acute disorder. Those patients who present psychosomatic disorders of long duration which are accompanied by severe organic change and extensive psychosocial disability generally prove resistant to treatment. The type of disorder will also influence prognosis. In general, psychiatric treatment is most effective in those disorders in which psychological determinants are most important. Thus primarily psychogenic physical disorders, such as impotence, diarrhea, and vomiting, have a relatively good prognosis with psychiatric treatment; while the treatment of other conditions, in which somatic determinants are relatively more important, such as hypertension and arthritis, has been far less effective.

Organ vulnerability to the physical concomitants of emotional arousal will depend on two factors—the nature of the patient's psychosomatic disorder, i.e., the "symptom choice," and the severity of the somatic illness. On the whole, patients are more resistant to the physiological concomitants of emotional arousal during the chronic and remittant stages of the physical illness than they are during the acute phase; therefore, psychiatric procedures should vary accordingly. At the same time, while this generalization applies to the majority of patients, there is some variation in certain disorders. Specific indications for various forms of psychiatric treatment are discussed below.

Physiological effects of treatment. Psychiatric treatment, by way of its impact on the patient's emotions, may result in profound physiological reactions. The physiological effects of psychiatric intervention do not usually prove significant in the treatment of general psychiatric patients. But they may be of crucial importance in the treatment of psychosomatic patients. Unlike the general psychiatric patient, psychosomatic patients are highly vulnerable to the adverse physical effects of emotional arousal. Psychiatric techniques which produce profound emotional responses are best used judiciously with such patients.

Psychophysiological factors in the treatment of psychosomatic disorders. The interaction between physiological and psychic factors constitutes another element to be considered in treatment. Often, the first task of therapy is to make the patient aware of the relationship between his emotional problems and his ulcer, hypertension, or skin rash, a relationship which is not always readily apparent. The next step involves the clarification of this relationship.

Individual psychophysiological reaction patterns vary widely and tend to be highly specific. The nature of the symptom, as well as the characteristics of the stimulus which evokes the psychophysiological response, requires careful evaluation in each individual case.

The physiological concomitants of affective arousal, which are assumed to play an etiological role in psychosomatic disease, do not involve the total reaction of the entire autonomic nervous system, but the discrete activation of specific autonomic functions. These activation patterns are characteristic of the individual and may be evoked by a wide range of stressful stimuli. Thus some individuals characteristically respond to a variety of distressing situations with sharply increased gastric hyperacidity, some with increased heart rate, and still others with increased dyssynchronous tension of the head and neck musculature. In other cases there is a degree of stimulus specificity as well. Thus, an individual may react with tension headache to the stimulus of difficult competition with peers, while rejection by a love object may evoke diarrhea.

The significance for treatment of the psychophysiological symptom. The significance of the role accorded the psychophysiological symptom in determining the conduct of psychotherapy is controversial and will depend on the psychiatrist's underlying theoretical assumptions. According to the specificity theory, the "symptom choice" or type of disorder dictates the nature of the interpretations made to the patient, as well as the extent of the therapeutic goals. Specific therapeutic recommendations are made because, according to this viewpoint, the different psychophysiological disorders are causally related to specific psychodynamic problems, which call for specific therapeutic maneuvers. For example, all peptic ulcer patients are assumed to suffer from unconscious dependency conflicts (which, theoretically, have their roots in conflicts that derive from the oral stage of psychosexual development). Accordingly, the resolution of these conflicts automatically becomes the goal of psychotherapy.

The lack of conclusive evidence to support this specificity hypothesis has led to the formulation of an alternate theoretical position. According to the "nonspecific" model, the nature of psychopathology cannot be predicted from the type of somatic symptom. Specific psychodynamics are not associated with specific psychophysiological disorders; and, consequently, psychiatric treatment procedure should not be influenced by preconceived dynamic formulations based on somatic considerations, but should be determined primarily on the basis of psychiatric considerations. Accordingly, the therapist is not justified in automatically assuming the existence of an "oral" problem in each ulcer patient and conducting psychotherapy on the basis of this assumption. To proceed in this manner would clearly do the patient a disservice if his anxiety actually derived from other factors. In fact, according to the nonspecific viewpoint, ulcer patients may suffer from conflicts which center around sexuality or aggression, and which originated during the anal or oedipal phase of psychosexual development. Or their anxiety may be

associated with difficulties in adapting to a current life situation, or with interpersonal problems that might best be handled therapeutically without the prior assumption of basic oedipal or pre-oedipal conflicts.

Many clinicians believe that psychosomatic patients relate to people whom they love in a pathological manner which makes them especially vulnerable to object loss and predisposes them to pathological psychophysiological reactions. Concomitantly, actual loss, or the fear of loss of the object is considered to precipitate the onset of many types of psychophysiological disorders. And, based on this premise, therapy is designed to gratify the patient's emotional needs temporarily in order to compensate for the loss (real or fantasied). At the same time, the long range goal of therapy is to permanently alter the patient's pathological object relationships. The effectiveness of this therapeutic approach in terms of the achievement of this goal, as well as the validity of the underlying hypothesis, awaits confirmation.

The significance for treatment of the stress-evoking stimulus. Formulation of an effective treatment plan also relies heavily on the astute assessment of the stimuli or circumstances which characteristically evoke the patient's pathological psychophysiological response. Stress-evoking situations may vary extensively in nature and intensity. At times, a realistic, readily apparent environmental frustration may evoke the pathological reaction; at other times, the crucial stimulus is highly subtle and best understood in psychodynamic terms. Helping the patient to become consciously aware of his individual psychophysiological reaction pattern and identifying the situations which typically precipitate this reaction may be very helpful.

The extent of psychiatric intervention depends, among other considerations, on the physiological reaction pattern. When the stressful stimulus is readily perceived and limited to an avoidable situation, guidance and environmental manipulation may prove sufficient psychiatric intervention. In other cases, the stimuli may be diffuse and subtle and arise out of distorted object relationships which make it difficult for the patient to avoid stress. Such patients may require extensive psychiatric treatment, aimed at changing basic patterns of relating to objects and other adaptational patterns.

Psychiatric considerations in the treatment of psychosomatic disorders. Of all the considerations determining the therapeutic approach to psychosomatic patients, psychiatric factors are perhaps the most important. For, in the last analysis, the psychiatric diagnosis and the nature of the patient's psychopathology will determine which techniques can be employed most effectively to alter the affective reactions that underlie the psychosomatic disorder.

For schizophrenic and borderline patients who present psychophysiological disorders, establishment of a supportive relationship, guidance, and administra-

tion of antipsychotic medication may constitute the optimal treatment plan. On the other hand, the treatment of choice for a neurotic patient whose psychophysiological symptom is associated with diffuse anxiety reactions may be reconstructive psychoanalytic therapy. In still another type of patient, the pathogenic conflict and anxiety reaction are evoked by a specific and avoidable situation. In such cases, anxiety reduction might be achieved most economically by guidance and environmental manipulation.

Therapeutic techniques. All of the various psychiatric treatment methods have been employed at one time or other in the management of psychosomatic disorders. Individual psychotherapy, group therapy, milieu therapy, and organic therapy all have a place in the treatment armamentarium. However, psychotherapy and pharmacotherapy appear to be the most useful treatment modalities for these disorders. Therefore, the following discussion is confined to consideration of some of the special problems inherent in the application of individual psychotherapy and pharmacotherapy to psychosomatic disorders.

Psychotherapy. As mentioned above, the psychotherapeutic encounter may have physiological effects upon the patient which are important in the therapy of psychosomatic disorders. Some of these effects are beneficial and are evoked deliberately; others are potentially harmful and should be avoided. Among the psychotherapeutic techniques that are commonly employed and which will be considered here from the viewpoint of their physiological effects, are the therapeutic relationship, ventilation, and insight therapy.

The supportive doctor-patient relationship. The establishment of a supportive relationship which permits emotional contact and gratification of the patient's dependency needs constitutes a psychotherapeutic procedure that is considered to be one of the most effective and rapid means of diminishing anxiety, with its accompanying physiological upheaval. This method of inducing physiological calm is of especial value during the acute phases of certain psychophysiological reactions. At such times the patient is extremely vulnerable to the physical effects of emotional arousal, and such rapid psychologically induced "tranquilization" can be of substantial therapeutic benefit and may make a significant contribution to the improvement of the physical disorder and the facilitation of medical therapy.

On the other hand, a major limitation of supportive psychotherapeutic techniques is that its calming effects are temporary and are generally limited to the duration of contact between the patient and the therapist. In addition, as mentioned above, psychosomatic patients are often highly sensitive to separation from the people who are important to them, and termination of treatment or a shift in the therapist's supportive attitude must be handled cautiously if exacerbation of the illness is to be avoided. However, a therapeutic relationship may be of temporary value in

helping the patient through a physical crisis, and in preparing him for more definitive types of psychiatric therapy in the future.

Ventilation. The frequently used psychotherapeutic technique of permitting the patient to "ventilate," i.e., to express emotionally laden material verbally, may be of potential value in certain psychosomatic disease states. Some patients can tolerate transient turmoil and benefit by the consequent calmer emotional state. On the other hand, expressing feelings of anger, fear, or frustration may also precipitate temporary emotional arousal which may be harmful to a medically vulnerable patient. Thus ventilation, like other therapeutic techniques, is best used judiciously with the potential impact of the possible physiological effects on the psychosomatic disease process kept clearly in mind.

For example, the overt expression of emotional arousal is characteristically inhibited in tension headache and some cases of bronchial asthma. In these disorders ventilation has been reported as beneficial in ameliorating physical symptoms and rendering medical therapy more effective. On the other hand, in certain severe illnesses, such as acute ulcerative colitis or coronary thrombosis, the temporary affective arousal which may accompany expression of emotionally charged material represents a potential physical danger and is contraindicated.

Insight therapy and interpretation. The ultimate goal of the psychiatrist is to diminish the patient's anxiety and thereby relieve the psychosomatic disorder. And, in some cases, effective reduction of the chronic anxiety which underlies the psychosomatic disorder can be achieved only by extensive change in a patient's general psychological adaptation or personality structure. To this end, the therapist may employ the techniques of insight therapy. Essentially, this consists of helping the patient to become aware of and resolve the fears, wishes, and conflicts which lie outside his conscious awareness, on the assumption that the conscious perception and resolution of these conflicts will ultimately result in beneficial behavioral changes and, concomitantly, improvement in the patient's somatic status.

The process of insight therapy often involves a temporary disruption of the psychological defenses that ordinarily serve to protect the patient from emotional upheavals. Therefore, when treating the psychosomatic patient, the psychiatrist must be sensitive to the potential somatic effects of anxiety, anger, and depression, which may be transiently evoked by the interpretation and uncovering of emotion-laden conflicts, and the concomitant disruption of psychological defenses. Even the protective mantle of the supportive therapeutic relationship, while helpful, does not afford complete protection against emotional arousal. While analysis of the patient's defenses and discussion of such distressing material as his unconscious wishes and fantasies may be necessary in

order to achieve the ultimate beneficial therapeutic changes, the temporary emotional arousal with its potential somatic upheaval may, in highly vulnerable patients, actually aggravate the psychophysiological process under treatment to a dangerous degree. The solution of the consequent therapeutic dilemma requires exploitation of fluctuations in the psychosomatic patient's vulnerability to the physical effects of emotional arousal.

Sensitivity to the physiological components of affective arousal is not uniform but seems to vary with the medical status of the patient. As mentioned earlier in this section, during acute phases of psychosomatic illness, the diseased organ may be highly vulnerable to the physical effects of emotional arousal, while resistance is greater during the remission phase. For example, the acutely inflamed colonic mucosa which is characteristic during the acute stage of ulcerative colitis is exquisitely sensitive to emotional arousal. Thus, during acute colitis, interference with psychological defenses and discussion or interpretation of stressful psychological material which may arouse anger and anxiety are considered to be detrimental and even potentially dangerous to the medical condition of the patient, whereas such techniques can often be utilized quite safely during the chronic phase of the illness, when the mucosa is not in a state of inflammation and is no longer as vulnerable.

In summary, the psychotherapeutic approach should be flexible; techniques should be shifted and changed frequently in accordance with variations in the patient's medical status. In a sense, the patient's physical symptoms can then serve as an "indicator" or warning signal: their exacerbation alerts the therapist to the fact that the psychic material evoked in therapy has endangered the physical well-being of the patient. The therapeutic emphasis can then be shifted from exploration to support.

During exacerbation and during the acute stages of the illness, psychiatric treatment generally focuses on the reduction of the patient's anxiety. Techniques of relationship therapy, reassurance, support, and, when appropriate, gratification of the patient's dependency needs and reinforcement of defenses are best suited to this purpose.

During the chronic phase, when the illness is in remission, the patient is in a better position to withstand the physical effects of affective arousals. At this stage, it is possible to administer more definitive psychiatric treatment in the form of insight therapy, where psychiatrically indicated.

Controversial issues. The goals and techniques of psychotherapy with regard to psychosomatic patients are the subject of some controversy. According to some psychoanalytically oriented writers, who assume a basic organ vulnerability in psychosomatic patients, the analysis of "id material," that is, techniques designed to bring deeply repressed impulses and fantasies to the patient's conscious awareness, are contra-

indicated in the treatment of psychosomatic patients. For it is assumed that this technique may precipitate acute exacerbation of the physical illness. These therapists suggest that interpretations be limited to "ego material," or distortions in the patient's adaptation to current life situations. The patient is partially aware of these distortions; they are unformulated, rather than repressed. However, this position is based on theoretical assumptions which themselves are the subject of controversy, inasmuch as they are not clearly supported by clinical evidence. Specifically, the nature of the vulnerable organic substrates have not yet been clarified.

The available clinical data seem to be more consistent with the alternate viewpoint, that the physical vulnerability of psychosomatic patients is highly variable. It fluctuates during the course of the illness and can be improved with medical treatment. Therefore, the goals and nature of psychotherapeutic maneuvers should be determined primarily by the psychiatric status within the limits imposed by each patient's specific physical vulnerability. Accordingly, when psychiatrically indicated and medically permissible, therapeutic techniques aimed at clarifying unconscious sexual and hostile wishes (i.e., "id material"), may be safely undertaken with benefit to the patient.

In fact, with specific reference to interpretation, on the basis of the clinical data accumulated to date, the only recommendation which seems warranted for psychosomatic patients concerns the interpretation of the psychic meaning of their psychophysiological symptom. In contrast to neurotic symptoms, such as conversion reactions, the psychophysiological symptom is not usefully conceptualized as a form of resistance, a discharge of "psychic energy," a psychological defense, or a symbolic representation of a psychic conflict. Interpretations attributing such functions to the psychophysiological symptom may have the undesirable effect of evoking feelings of helplessness, anxiety, and hostility in the patient. Actually, psychophysiological disorders tend to arise when psychological defenses deteriorate. Therefore, the patient's symptom can be viewed most constructively, by both therapist and patient, as a concomitant of emotional stress, the sources of which should be explored in the therapeutic process.

It has been noted, however, that psychophysiological symptoms, like many symptoms of ordinary physical illness, may *secondarily* acquire defensive, resistive, and symbolic meanings. The utilization of somatic disability in the service of resistance to psychotherapy and to realistic life adaptations can be dealt with by the psychotherapeutic techniques typically employed in dealing with the phenomenon of secondary gain.

Specialized treatment procedures. Several specialized techniques for the treatment of psychosomatic disorders have been developed. An interesting one among these is Margolin's "anaclitic therapy." This is a

method of individual psychotherapy for psychosomatic disorders, based on the controversial "regression" hypothesis, which states that psychosomatic patients regress to early levels of psychosexual development, physiologically as well as psychologically, in the face of stress. The consequent immaturity of the physiological response pattern is assumed to result in psychosomatic disorders. Accordingly, the anaclitic method is designed to encourage the patient to develop extreme dependency on the therapist and to foster "regression" to an infantile level of psychological and physiological adaptation. An attempt is then made to enable the patient's reintegration on a more mature and adaptive level. In general, therapeutic results with this technique have been disappointing, as have the results of other specialized techniques for the treatment of psychosomatic disorders.

Pharmacotherapy. The psychiatric treatment of psychophysiological conditions is not limited to individual psychotherapy. Other treatment modalities, notably pharmacotherapy, also have a place in the treatment armamentarium.

Psychoactive drugs provide the psychiatrist with a powerful tool for reducing the anxiety that is so harmful to the psychosomatic patient. While psychological treatment methods attempt to reduce anxiety by altering its psychological determinants, such as the patient's unconscious conflicts or inadequate adaptational techniques, pharmacological treatment acts to inhibit the neural substrates that mediate emotional arousal and thereby to diminish anxiety directly, regardless of its origin. Admittedly, drug-induced "tranquilization" is temporary, lasting only as long as the drug is present in the brain, and it does not alter the psychic determinants of the patient's anxiety. Nevertheless, pharmacotherapy is sometimes an extremely useful adjuvant to treatment as it acts rapidly, when time is of essence, to protect the psychosomatic patient against the physical dangers of emotional arousal.

Tranquilizers are the most useful psychotropic drugs for the treatment of psychophysiological disorders. However, some investigators are also exploring the therapeutic possibilities of the antidepressants.

Tranquilizers. Antipsychotic drugs of the phenothiazine type are often effective therapeutic agents in the management of both the behavioral and the psychophysiological symptoms of the schizophrenic and "borderline" patients who also present psychosomatic disorders. These drugs often prove to be the most effective means available for reducing the schizophrenic patient's anxiety. They are useful for the management of the acute stages of illness as well as for maintenance therapy for chronically ill patients. However, psychopharmacological therapy has somewhat less to offer the nonschizophrenic psychosomatic patient as the "tranquilizing" effects of phenothiazine drugs with such patients are questionable.

The so-called "minor" tranquilizers, notably of the chlordiazepoxide group, are sometimes useful in the

treatment of nonschizophrenic psychosomatic patients, insofar as they help to diminish the patient's potentially harmful anxiety during periods of acute stress. But these drugs appear to be more effective for acute anxiety states than for chronic states of anxiety; thus, they are not often useful for maintenance therapy of the chronically anxious psychosomatic patient.

Antidepressants. It has been reported that antidepressant medication is effective in the treatment of some patients with psychogenic somatic complaints, notably enuresis and gastric complaints. These reports have been interpreted as evidence in support of the hypothesis that such somatic symptoms represent "masked depressions," that is, that they are associated with and express underlying depression. Final evaluation of the validity of this hypothesis and of the efficacy of antidepressant therapy in psychophysiological conditions awaits further experience.

Results of the psychiatric treatment of psychophysiological reactions. Psychiatric treatment cannot alter basic organ pathology, if it is present. Rather, it attempts to reduce the stress to which the diseased organ is vulnerable, and in this respect, psychiatric treatment is often valuable. The rationale for including psychiatric treatment in the therapeutic regimen of psychosomatic disorders, such as ulcer and asthma, is based largely upon the clinical impression of its effectiveness and upon theoretical assumptions. Unfortunately, few documented and controlled studies are available to provide reliable "hard" data concerning the effects of psychiatric treatment of psychosomatic conditions.

A notable exception is the recent well designed study by O'Connor et al., which demonstrated that inclusion of psychiatric treatment in the total management regimen of ulcerative colitis patients resulted

in significant medical improvement, in comparison to the medical status of patients in the control group which did not receive psychiatric treatment. This study is of special interest because it employed physical criteria (i.e., the condition of the colonic mucosa, number of bowel movements per day, etc.) to evaluate the effects of psychiatric treatment.

It is hoped that future research efforts will further exploit the unique opportunities for evaluation of psychiatric treatment procedures on the basis of the objective and quantifiable variables provided by the somatic signs and symptoms of the psychophysiological disorders.

THE PSYCHIATRIC SYNDROMES

Chapter 31

Psychiatry and Other Specialties

31.1 THE CONCEPT OF PSYCHOGENICITY IN MEDICINE

HELEN S. KAPLAN, M.D., PH.D.

Introduction

It is generally agreed that psychological factors play an important role in the genesis of many medical disorders. Efforts to assess the precise magnitude of the problem have been hampered by the fact that the criteria of psychogenicity are highly ambiguous. However, the available data indicate that psychically determined disorders are highly prevalent in medical practice. Thus, although the figures from epidemiological studies vary widely, it would appear that approximately one half of the patients who seek medical help for physical complaints have a significant underlying psychiatric problem.

Despite its importance however, the concept of psychogenicity in medicine is not always clearly defined.

Unfortunately such different types of psychogenic somatic disorders as peptic ulcer, hypochondriacal complaints, and conversion symptoms are often erroneously included in a single category without an appreciation of the important differences between them. However, the precise differentiation of the various clinical categories of psychogenic somatic disorders and of their underlying mechanisms is essential for their clear understanding upon which ultimately their effective treatment rests.

Definition. The terms "psychosomatic," "psychogenic," and "psychophysiological" are thus in need of precise definition. In this discussion, the terms "psychosomatic disorder" and "psychophysiological disorder" are used interchangeably and are synonymous with the cumbersome official American Psychiatric Association's designation of "psychophysilogic and visceral autonomic disorders." On the other hand, the term "psychogenic" is used here to signify that the etiology of a disease, sign, or symptom, or its progress or exacerbation, is, at least in part, psychologically de-

termined. As previously mentioned, psychological factors can produce somatic complaints through various mechanisms, and several clinical categories of psychogenicity can be differentiated. Thus, psychosomatic is not synonymous with psychogenic; rather, psychosomatic disorders represent one type of psychogenicity.

Other clinical categories of psychogenic somatic complaints include malingering; hypochondriasis; conversion reactions, i.e., hysteria; and self-inflicted physical disease. They share in common the fact that the various somatic complaints and symptoms which are associated with each of these entities have a substantial psychogenic component.

The clinical categories of psychogenicity are discussed in detail elsewhere in this book. They are summarized briefly below mainly for purposes of definition and comparison and to illustrate the complex interrelationship between psychological and physiological factors in medicine.

Clinical Categories of Psychogenicity in Medicine

Self-inflicted disorders. At any one time, a large proportion of the beds in a general hospital are occupied by patients *who suffer real, and often severe, somatic disease as a direct consequence of their own psychopathological self-destructive behavior.* That is, in a sense, the disease is self-inflicted. It is generally recognized that psychiatric patients, impelled by unconscious self-destructive motives, often destroy their relationships, careers, and sexuality in ingenious and subtle ways. However, the individual can also use his body and his health as a vehicle for self-destruction.

In some instances, as in the case of self-inflicted damage resulting from suicide attempts, this masochistic process is obvious. Less frequent but equally dramatic examples of self-destructive behavior are the self-mutilations displayed by some severely disturbed patients, such as self-castration, hair pulling, head banging, and self-inflicted skin lacerations. In these cases, the patient is fully aware of his desire to inflict damage upon himself, although usually he has no insight into the underlying psychological factors which motivate his behavior. More subtle—and common—are those cases where the patient is *not*

aware of his self-destructive tendencies or of his underlying motivations. He does not see his illness as being self-inflicted.

In fact, the possible motives which underlie self-destructive behavior are numerous and complex. Some patients are motivated by a sense of guilt and a wish for punishment for real or fantasied "wrongs." In other cases, the individual unconsciously cultivates pain and illness, in an attempt to control a relationship or to gain love. Self-destructive behavior may represent an unconscious attempt to avoid an even greater "danger." For example, a patient may overeat, and so expose herself to the destructive physical effects of obesity, in order to avoid what she considers the greater danger of sexual temptation. In contrast, in still another group of patients self-destructive effects are the coincidental sequelae of behavior which do not derive from masochistic motivations. Obesity may also serve to illustrate this type of self-destruction. The obese patient damages her health, her sexual attractiveness, her social relationships, and her career by eating excessively. In some cases, as mentioned above, this behavior is motivated by profound unconscious self-destructive desires. In other cases, the patient's compulsion to eat is not motivated by a wish to harm herself but may stem from her need to control the emergence of intolerable anxiety or to ward off painful feelings of depression.

Clinical manifestations. This category of psychogenicity, whereby self-destructive behavior results in organic injury, encompasses a wide variety of disorders which include, besides obesity, alcoholism, with its many serious medical complications; addiction to narcotics and various other drugs; accident proneness, involving a wide variety of medical and orthopedic complications; and criminal abortion. Even habitual smoking, with its attendant risk of cardiovascular and respiratory disease, may be included in this category.

Treatment. Treatment methods and results vary with the problem presented by the individual patient. Behavioral or symptomatic therapy such as hypnosis and conditioning techniques which are restricted to elimination of the specific self-destructive act may be effective in some cases. This approach has been used with variable results in such conditions as smoking, obesity, and narcotic addiction. When psychotherapy is employed, treatment may be limited to fostering the patient's conscious perception of the self-destructive consequences of his behavior, and the mere realization that his behavior has self-destructive effects may produce the desired results. In other cases, however, the patient must acquire some insight into the motives which underlie his self-destructiveness before he can alter his behavior.

Malingering. Malingering refers to the conscious simulation of illness or disability. It is included in this discussion of psychogenicity because it must be considered in the differential diagnosis of many physi-

cal complaints. The motive is usually consciously recognized gain. For example, the criminal who is trying to avoid a prison sentence may disclaim responsibility for his actions by simulating a psychiatric disorder; the soldier may feign physical illness to avoid the dangers of combat. Both the criminal and the soldier are consciously aware of the fact that they are malingering. However, the more complex factors underlying the criminal behavior in one case and excessive fear in another, which motivated their malingering, may be much less clear.

Individuals who have no diagnosable psychiatric disorder may be malingerers. However, malingering is often seen in sociopathic individuals, and it may even mask other more serious psychopathology. For example, in pseudopsychopathic schizophrenia, malingering may form a prominent part of the syndrome and may be considered as an expression of the underlying schizophrenic process.

Clinical manifestations. The nature of the simulated symptoms tends to vary with the type of gain sought. Children who wish to stay home from school often complain of abdominal pains; persons seeking compensation payments may complain of symptoms related to their injury. When the gain sought is obvious, malingering is relatively easy to detect. On the other hand, the symptoms simulated by patients whose motivation is more obscure and does not involve clearly recognized gain are highly varied, and it is often difficult to arrive at the diagnosis of malingering in such cases.

Great ingenuity and effort may be displayed by simulators and all manner of vague pain, vertigo, and weakness and dysfunctions have been simulated. A favorite symptom is fever of unknown origin, which patients simulate by hiding extra thermometers which they heat with light bulbs to produce an apparent increase in temperature.

Treatment. Not surprisingly, the malingering patient may evoke an angry reaction from the physician who has devoted a great deal of energy to the diagnostic work-up and care of the patient and now feels that he has been exploited. Unfortunately, however, this reaction may interfere with his objective evaluation of the psychiatric aspects of the case. A therapeutic attitude is important, because malingering may be a symptom of the patient's deep underlying distress, which may often be relieved by psychiatric treatment.

Hypochondriasis. Hypochondriasis may be defined as a preoccupation with and exaggerated concern or anxiety about an imagined or real somatic sign or symptom. The patient's manifest concern may focus on a part of his body which is functioning normally, a mild illness, or the physiological concomitants of an emotional state which he has misinterpreted as symptomatic of a dangerous medical condition. Although the patient is firmly convinced that he is physically ill, actually his problems are of psychic origin.

On a psychodynamic level, a hypochondriacal symptom may be described as an anxiety or depressive equivalent. The true source of the patient's anxiety is seldom his somatic symptom but usually stems from a variety of deeply personal and often unrecognized factors, such as approaching old age and death; the impending or feared loss of a love relationship; or deteriorating psychological defenses in the face of emerging sexual or aggressive impulses. In hypochondriasis, the intrapsychic anxiety or depression is displaced onto a bodily organ or function without the patient's awareness and is expressed in the form of concern about a somatic problem. At times, the choice of the organ or function which is the target of hypochondriacal concern has a symbolic relationship to the underlying problem. For example, adolescents with sexual conflicts commonly show great concern about venereal disease. In any event, it must be emphasized that hypochondriacal patients are not consciously malingering; they are often anxious and in distress.

Clinical manifestations. Common hypochondriacal symptoms currently seen in the general hospital include complaints about bowel function, chest pain, rapid pulse, dyspnea, abnormal sexual functioning, and fears of serious disease, such as venereal infection, cancer, or heart disease. Psychiatric disorders also may be used in the service of hypochondriasis. Adolescents, at this difficult stage in their development, frequently become concerned about the possibility that they may be harboring schizophrenic or homosexual tendencies.

Treatment. Treatment which is directed at the manifest somatic complaints and includes reassurance regarding the patient's physical health and the administration of medication to relieve medical symptoms (analgesics, laxatives, etc.) is generally unsuccessful because it cannot alleviate the patient's underlying anxiety. Psychiatric treatment toward this end is likely to yield better results.

At the same time, however, hypochondriasis, as well as anxiety and depression which it often masks, is not a specific psychiatric disorder, but rather a symptom of psychological distress. In clinical practice, it is encountered in a wide range of psychiatric conditions, including the psychoneuroses, depressive reactions, schizophrenias, and organic conditions, such as arteriosclerotic brain disease. Indeed, hypochondriasis may be present in normal individuals during periods of stress. Therefore, no specific recommendation can be made regarding the conduct of therapy which must be directed at the specific underlying psychiatric disorder.

Conversion reaction (conversion hysteria). This most dramatic of psychogenic conditions is seldom seen in its pure clinical form today. However, conversion reactions may contribute to the clinical picture of many disease states.

A conversion or hysterical reaction refers to a so-

matic symptom, motor or sensory, which is not caused by physical pathology but is due to unconscious psychological factors, such as conflict, trauma, or frustration. Conversion reactions are neurotic symptoms which are expressed in the form of somatic complaints. The patient is *not* consciously malingering and often shows little distress (the classical *la belle indifférence*) about his symptom although it may restrict his functioning markedly.

A detailed discussion of psychoanalytic hypotheses regarding the mechanism of conversion lies beyond the scope of this section and is presented elsewhere in this volume. A simplified explanation of this complex phenomenon is included here primarily to permit comparison between hysterical and psychophysiological reactions.

Theories regarding the mechanisms of conversion reactions operate on a purely psychological level of description and typically employ such psychodynamic constructs as unconscious conflict, repression, regression, symbolism, psychological defense mechanisms, and the stages of psychosexual development. Essentially, the conversion symptom is conceptualized as resulting from a pathological solution of a psychic conflict, the issues of the conflict being outside of the patient's awareness, or "unconscious." It is further postulated that there is a symbolic relationship between the unresolved conflict and the conversion symptom, whereby both the repressed wish and the inhibiting force are expressed in the neurotic symptom. Conversion also has the important function of serving as a psychological defense, in that it reduces or prevents the anxiety which would arise were the repressed wish to enter consciousness.

According to the classical Freudian school of thought, the unconscious conflict involved in conversion reactions always stems from repressed sexual impulses, specifically unresolved oedipal wishes, and involves a regression to the phallic stage of psychosexual development. According to other theoretical viewpoints, conflicts involving aggression and dependency, which derive from pre-oedipal levels of psychosexual development, may also result in hysterical reactions. Indeed, it may be speculated that anxiety resulting from interpersonal difficulties or situational stress, which are not related to neurotic conflicts deriving from either the oedipal or the pre-oedipal stages, may also be handled by conversion by certain patients. Furthermore, while according to the classical viewpoint conversion symptoms are said to occur in "hysterical" personalities, such symptoms may also be seen in other personality types and in such diverse psychiatric disorders as mixed psychoneurosis, and schizophrenia.

Clinical manifestations. The form taken by conversion symptoms seems to be sensitive to social factors and tends to change with time and place. The dramatic "grand" hysterical seizures which occurred at the turn of the century in Vienna are rarely encoun-

tered today. Symptoms seen in current practice include various paralyses, pareses and flexures, tremors and abnormal movements, convulsions, sensory deficits, vomiting, swallowing difficulties, sexual anesthetics, and rather exotic disturbances in behavior.

Treatment. The treatment of choice is psychotherapy, which is usually aimed at analyzing and interpreting the defensive meaning of the conversion symptom and at attempting to foster insight into the nature of the underlying unconscious conflicts, in order to permit their rational resolution. Successful removal of the conversion symptom directly, without resolution of the underlying psychopathology by means of suggestion or hypnotism or with the aid of intravenous barbiturates, has also been reported. However, the results of such methods in terms of the patient's global status are controversial. Some therapists report good results with enhanced feelings of worth and better global functioning. In other cases, removal of the hysterical symptoms has precipitated serious deterioration of the patient's psychiatric condition in the form of overt psychosis and depression.

Psychophysiological disorders (psychosomatic disorders; psychophysiological and visceral autonomic reactions). *A psychophysiological or psychosomatic symptom or disease always involves some actual somatic pathology or dysfunction which is caused, at least in part, by psychic factors.* According to this concept of psychosomatic disorders, psychic factors are seen as one of several contributory determinants which combine to result in the final disease state. Theoretical and therapeutic concepts of psychophysiological disorders are exceedingly complex and are considered in detail elsewhere in this book. The present discussion is confined to a brief description of basic principles.

The basic mechanism by which psychic factors contribute to such organic disease is essentially simple: psychophysiological disorders result from the physiological concomitants of affective states. Emotional arousal is normally accompanied by profound physiological reactions, involving changes in vascularity, secretion, motility, and tone of every organ and system of the body which is under nervous and hormonal control. Acute emotional reactions, if quickly resolved, normally cause no harmful effects in the healthy organism. However, chronic, unrelieved, and frequently recurrent states of emotional arousal, with their accompanying physiological upheaval, or affective states accompanied by excessive or pathologic physiological arousal may result in the organic pathology of psychosomatic disorders in those susceptible individuals who have an organic vulnerability to the physiological effects of emotion.

Although affective reactions, such as rage and depression, may be involved in the genesis of psychophysiological disorders, the affect most commonly implicated is chronic anxiety. Psychiatric treatment tends to focus on one highly prevalent source of such

anxiety, namely intrapsychic conflict, the nature of which is usually outside the patient's awareness. Often such conflict involves vicissitudes in interpersonal relationships, especially the relationships of the patient with a significant love object.

Thus, given a certain predisposition, psychosomatic symptoms may be expected to appear when the patient responds with anxiety to some stress in his life situation because his adaptive capacities are inadequate and his psychological defenses have failed to protect him against excessive emotional arousal.

Clinical manifestations. Psychophysiological reactions may affect every organ system of the body. Some of the common symptoms and diseases which are generally believed to have important psychosomatic components are as follows: (1) cardiovascular: psychophysiological cardiac reactions, essential hypertension, vasomotor syncope; (2) gastrointestinal: dysphagia, dyspepsia, peptic ulcer, ulcerative colitis, ileitis, diarrhea, constipation; (3) respiratory: bronchial asthma, vasomotor rhinitis, dyspnea, hyperventilation; (4) genitourinary: impotence, premature ejaculation; (5) obstetric and gynecological: menstrual disturbances, frigidity, sterility, disturbances in labor, disturbances of lactation; (6) endocrine: thyroid disturbances, diabetes; (7) skin and allergy: pruritis, eczema, various dermatoses; (8) musculoskeletal disorders: back pain, rheumatoid arthritis; and (9) miscellaneous psychophysiological conditions: headache.

Treatment. Psychiatric therapy cannot alter the organic substrate; rather, its goal is to diminish the pathogenic anxiety to which the patient is vulnerable. Since many types of individuals are subject to chronic and recurrent unrelieved emotional arousal, it is to be expected that psychosomatic symptoms will be manifested by patients with widely differing psychiatric diagnoses. And, in fact, psychophysiological reactions are seen in relatively normal individuals who are experiencing some transient stressful adaptations, in neurotics with deeply disturbed object relationships, and also in disorganized psychotic patients. The choice of treatment method depends on an accurate assessment of the specific underlying psychopathology, and is limited by the patient's physical vulnerability.

Comparison of Psychogenic Somatic Disorders

The criteria for differentiation of psychophysiological reactions and other types of psychogenic somatic disorders, especially conversion reactions, may be summarized as follows:

Organic pathology. Psychophysiological disorders always involve organic pathology and/or pathological functioning. Such organic damage is totally absent in conversion reactions and, if present in hypochondriasis, is a secondary consideration.

Symbolic meaning. In contrast to hysterical and hypochondriacal symptoms, the psychophysiological

symptom is not a neurotic symptom and has no primary symbolic meaning for the patient (except as such meaning is acquired secondarily). Hypochondriacal symptoms and symptoms of malingering may or may not have a primary symbolic meaning.

Relation to anxiety. Psychophysiological symptoms do not serve as psychological defense mechanisms; i.e., such symptoms do not diminish anxiety or tension. Rather, it is when the psychological defenses fail to reduce anxiety that psychosomatic symptoms, which represent the physiological concomitants of such anxiety, appear. Conversion symptoms, on the other hand, serve as a defense against anxiety. Hypochondriacal symptoms, while being anxiety equivalents, also serve to contain or limit the anxiety. Finally, malingering may help the individual to avoid anxiety-evoking situations.

Multicausality. While psychic factors constitute the primary determinant in such psychogenic disorders as conversion reaction, hypochondriasis, and malingering, and in self-destructive behavior, a psychosomatic disorder is always the result of multiple somatic as well as psychic determinants.

Autonomic and voluntary nervous control. According to the classic viewpoint, conversion symptoms always occur in the sensory or voluntary motor systems, whereas psychophysiological reactions always affect organs innervated by the autonomic nervous system. Alexander included such a differentiation between visceral and sensorimotor involvement in his original distinction between psychosomatic and conversion symptoms, which has been generally accepted and is reflected in the American Psychiatric Association nomenclature, "psychophysiological and visceral autonomic disorders." While this concept holds true in many instances, its universal validity should be questioned. Such conditions as tension headaches and certain cases of low back pain represent the concomitants of the increased striated or voluntary muscle tension which accompanies affective arousal in some patients and thus might best be classified as psychophysiological reactions. Conversely, pain resulting from the psychological mechanism typically attributed to hysteria or conversion is often experienced as originating in viscera innervated by the autonomic nervous system.

Multiple Mechanisms

Five different kinds of psychogenicity have been described to illustrate some of the various mechanisms by which psychic factors contribute to medical disorders. For the didactic purpose of clarification discrete clinical categories have been separated. In practice most cases are of mixed origin, in that several psychogenic components may contribute to any one case. For example, a hypochondriacal patient may be concerned about death and preoccupied about cancer but may also have an actual psychophysiological condition, such as a duodenal ulcer.

Combinations of psychophysiological and conversion reactions are also common. Thus, for example, after gastrectomy for a peptic ulcer which is a psychophysiological condition, some patients continue to complain of epigastric pain. The subsequent postgastrectomy syndrome which now occurs in the absence of the organic substrate may be attributed to a conversion mechanism.

Suggested Cross References

More detailed descriptions of the self-inflicted disorders may be found in the following sections: obesity, Section 30.3; accident proneness, Section 30.13; habitual abortion, Section 30.8; addictions, Sections 27.1 and 27.2; and alcoholism, Section 27.3. Malingering is further discussed in Chapter 50 on industrial psychiatry; additional information regarding hypochondriasis may be found in Section 32.3, while Section 23.2 contains a detailed discussion of conversion. Current concepts of psychosomatic medicine are presented in greater detail in Section 29.3. The reader may obtain further information regarding the treatment of psychophysiological disorders in the sections in Chapter 30 which deal with the specific disorders and in Section 30.15 on the treatment of psychophysiological disorders. Psychosomatic disorders in children are described in Section 41.2.

31.2 PSYCHIATRY AND MEDICINE

STANLEY M. KAPLAN, M.D.

By broad definition, consideration of the relationship between psychiatry and medicine refers to the role of psychological factors in the etiology, onset,

and course of somatic illness, and to the patient's psychological reactions to the experience of illness. While the precise mechanisms which underlie the interaction between psychological and physiological processes are not always known, it is generally recognized that psychological factors, which may be psychosomatic or somatopsychic in sequence, or both, to some extent, play a significant role in almost all illnesses. The psychophysiological mechanisms which are operative in specific illnesses and the general concept of psychogenicity in medicine are discussed elsewhere.

This section will attempt to explore still another facet of the "mind-body problem." More specifically, this discussion will focus on the following elements: (1) the medical patient's psychological reactions to consultation and treatment, and possible physiological concomitants; (2) the physician's psychological functioning (and the psychological role of those with whom he works and consults); (3) the interaction between patient and physician; and, finally, (4) the ways in which these factors may foster or impede the patient's recovery from or adjustment to his medical illness.

These variables will be considered in the context of: (1) the office visit; (2) hospitalization; (3) discharge from hospitals; (4) diagnostic procedures; (5) treatment; (6) chronic invalidism and rehabilitation; and (7) death. Obviously, each of these situations has many psychological ramifications; consequently, this discussion is limited to consideration of representative phenomena.

The Office Visit

Psychological implications of somatic dysfunction. The patient's psychological status prior to his initial visit to the doctor's office is often as important as his reactions to the visit itself. More specifically, if the patient has a psychological need to deny his illness, he may delay seeking medical attention and, as a result, lose precious treatment time while his disease progresses to a more serious or irreversible stage. The implications of this reaction for a patient with a malignancy are obvious, but it can be equally dangerous for the patient with crushing substernal pain, who procrastinates on the basis that "it's probably only indigestion," and the patient who attributes his melena to "something dark I ate." People deny illness for a number of reasons. In some instances, the disruption of normal physiological function is experienced as an overwhelming threat. Unconsciously, it may mean a dreaded loss of instinctual control. It may reactivate unconscious fears of castration, fears of separation from loved ones, and the threat of passive submission to others. Some patients, therefore, try to "wish" their symptoms away, rather than confront disease and call a doctor. Furthermore, the physician may unwittingly play into his patient's delaying tactics, if he has and conveys an attitude of

intolerance toward patients who "give in" to illness too quickly and without a "struggle," if he tends to overalarm his patients about symptoms, or if he sounds annoyed when they call for an appointment when his schedule happens to be particularly busy.

In contrast to those patients who try to avoid medical consultation, hypochondriacal patients may, of course, seek reassurance from their physicians with unnecessary frequency. However, this may present a less serious problem for the physician as well as the patient, although it may be more overtly annoying for the physician. The fact remains that these patients, at least, establish communication with the doctor.

Once he has arrived at the physician's office, other important inner and outer stimuli affect the patient. Even if he comes to the office for a routine physical examination, he will probably be anxious as he awaits his turn. And if the patient is consulting a doctor because he is experiencing unfamiliar symptoms, his anxiety will be compounded: "What will the doctor find?" "Will I have to go to the hospital?" "Will he hurt me?" "What about the expense of all this and the time off from work?"

Psychological reactions to diagnosed illness. In the face of the stresses of medical illness, it is very likely that the patient will regress to less mature forms of behavior, the degree of regression depending upon the nature and severity of the illness, the patient's early life experiences, and the quality of the doctor-patient relationship. In general, however, certain immature character patterns which are reasonably well attenuated during periods of health may emerge with particular clarity when illness strikes. For example, profound regression may be manifested by the stunned, withdrawn, uncommunicative behavior of one patient or in another's guarded suspicion of the physician. Other behavioral patterns may be similarly interpreted as indicative of regression to earlier levels of psychosexual development. The patient may "plead" for care, attention, and love, or he may demand it aggressively; both modes of behavior reflect the reactivation of infantile oral conflicts. In other cases, anal conflicts may find expression in behavior which ranges from extreme self-control, obedience, and cooperativeness to rebelliousness and outbursts of temper. Finally, evidence of unresolved problems associated with the phallic level of development may appear in one patient's dread of being hurt physically and in another's wish to compete with and take over the doctor's job. Whatever form the patient's behavior may take, its regressive components are evident; that is, such behavior is usually motivated by the patient's wish to have the physician "take over," in the role of a confident, authoritative, omnipotent, protective parent who will safeguard him during his illness.

These reactions are not necessarily restricted in time to the patient's first office visit, of course. They

may occur at any point in the course of treatment. Increased symptomatic discomfort, hospitalization, surgery, and diagnostic procedures must, inevitably, have some psychological impact, which may elicit a pathological reaction from the patient.

Concomitantly, the tolerance, flexibility, and understanding which the physician demonstrates in his responses to these reactions in his patients will foster such regressive tendencies or reduce them to a minimum. And his responses will depend, in turn, on his capacity to look beyond the frequently exasperating surface behavior of his patients. Almost any physician can deal satisfactorily with patients whose neurotic patterns happen to mesh well with his own personality needs. The quality which distinguishes the exceptional physician is his ability to deal with the unpleasant situation, with the problem patient, when this requires investigation of his own reactions so that he can better understand the subtleties of his relationship with the patient.

Evolution of the therapeutic relationship. The therapeutic relationship between the physician and his patient evolves during the initial office visits. This often requires working out problems which could interfere with their mutual goal of restoring the patient's health. The evolution of this relationship can be depicted as follows. Two people, separated by some distance, begin to walk toward each other. As they get closer, they look each other over, and at times they spar to test out reactions and counter-reactions. Ultimately, they stand opposite each other, and at this point, they may choose to remain at a stalemate, uncommitted, in a relationship of mutual distrust, in an endless toe-to-toe battle, in a clinging dependency of the patient on the physician, or in some other unproductive type of relationship. On the other hand, they may both turn in the same direction and join in a cooperative venture along the road of complete evaluation and treatment of the illness. This road will have its pitfalls, but if the relationship they have established is strong enough, it will withstand the jolts which tend to disrupt it.

Other psychological stimuli

The out-patient treatment setting. The treatment setting presents other psychological stimuli which will affect the patient's reactions to the physician and to his illness. The attitudes of the nurse and receptionist, as well as other personnel, can sharply influence the patient's response. Curtness leads to distrust; too informal an atmosphere will lead to concern as to whether his illness will be taken seriously enough. A cold, impatient response to a phone call for an appointment or an inquiry about medication can play havoc with the relationship the physician has worked so hard to develop. The cleanliness and general appearance of the office, the time the patient must spend waiting to see the physician,

the sounds emanating from the treatment room, even the vintage of the magazines in the waiting room contribute to the patient's concept of what his doctor feels toward him. All these stimuli can evoke feelings of positive acceptance and reassurance, on the one hand, or feelings of frustration and anger, rivalry and jealousy, and alarm and fear, on the other. Such feelings often carry over into the relationship with the physician: they influence the patient's confidence in the physician, his cooperativeness, and his ability to relate personal history, and they may evoke physiological responses which are reflected during the physical examination.

History taking. The history-taking phase of the initial office visit brings physician and patient together in close interpersonal contact, and the atmosphere in which it is conducted should contribute to the optimal functioning of both. It is particularly important that this interview take place in a quiet, relaxed milieu, conducive to introspection, so that the patient may determine and describe his internal physical sensations as accurately as possible and, in addition, try to remember specific factors which were associated with the onset and exacerbation of symptoms. The physician may also ask him to describe psychological reactions and interpersonal relationships which have influenced the course of his illness. If the patient feels rushed, or if his account is interrupted too frequently when the physician is called away to see other patients, to answer the telephone, to answer the nurse's questions, or whatever, his ability to provide the vital information the physician needs for diagnosis will be seriously hampered. It is equally important that the physician be able to give the patient his full attention, without distraction, if he is to interpret and integrate the data supplied by the patient. Ample time must be assigned for this purpose.

Privacy is essential, of course, not only because the intrusions are distracting, but also because the patient may be relating highly personal information. There are few things more distressing to a patient than to have his illness made public. If he has the feeling that others can overhear his conversation with the doctor, he may omit pertinent details or distort the history he relates to the physician. In fact, those patients who are seated where they can overhear another patient usually find this experience equally distressing. It can be embarrassing to the listener, and it can elicit the uneasy feeling that he may well experience the same fate. In this connection, it is important that files (office and hospital) be kept confidential, and that everyone working in the office be thoroughly aware of his responsibility toward patients in this regard. Needless to say, the physician, himself, must rigidly protect the privacy of the patient's communications and other information he has about the patient's illness.

The problems inherent in obtaining a history from

a patient with physical complaints differ from those encountered during the initial interview of the psychiatric patient who recognizes that he has an emotional problem. The psychiatric patient is prepared to launch into a description of his personal problems and is usually restrained only by unconscious resistances over which he has little control initially. In contrast, while the medical patient is willing to talk about the physical manifestations of his illness, he is usually reluctant to reveal information, which may be equally relevant, concerning his thoughts, fears, behavior, and interpersonal relationships. This problem may be complicated if the physician is embarrassed and reluctant to become involved in matters which he considers to lie "outside his domain." And, assuming that the physician has worked out his own problems in this regard, the problem arises as to how he can encourage the patient to pursue this line of thought. The physician's apparent interest in such details and his willingness to listen may be enough. On the other hand, at times it is necessary to explain to the patient why it is important to review his personal life. A simple explanation to the effect that it is important for the physician to know the patient as a person in order to understand his illness may suffice. Other patients, who are less sophisticated, may require a more elementary approach. In such cases, it may be helpful to emphasize the fact that emotions normally evoke certain physical reactions in all of us and then to demonstrate this hypothesis by citing some familiar psychophysiological correlations, such as embarrassment and blushing, fear and trembling, rage and sudden pallor, disgust and nausea. The physician can proceed from this point to remind the patient that people with peptic ulcers or hypertension may become ill when they are annoyed. These introductory illustrative statements may make the difference between eliciting the patient's cooperation in this connection and arousing the feeling that the physician is just being "nosey."

The physical examination. The physical examination is often the most highly charged aspect of the office visit. On the one hand, it arouses the patient's concern about the disease process the physician may discover, which may or may not be realistic. On the other hand, the prospect of being exposed, inspected, and probed by another human being (regardless of his professional status) may give rise to irrational feelings of resentment, fear, and helplessness. Thus, for example, the patient who watches the face of the physician so intently as he uses his stethoscope may be thinking: "Is there anything wrong with my heart?" "Why did he frown just then?" "Mother had heart trouble. Do I?"—and so on, endlessly. The patient may be frightened: "Will he press that sore spot?" "If he pushes that stick back in my throat any farther..." Or the patient may feel embarrassed. Obviously, adequate draping is necessary, and certain phases of the examination should be conducted in the

presence of the nurse. Some women are terrified by a vaginal examination because of unconscious rape fantasies; rectal examination can mobilize the deeply hidden homosexual concerns of some men. It is important for the physician to be aware of the multiple psychological meanings of specific aspects of the physical examination and of the fact that the anxiety or tension precipitated by these procedures can affect the very physiological functions he is observing.

The physician should also be aware of his own attitude toward the physical examination. Does he consistently avoid performing some necessary procedures because he is squeamish or overcautious? Does he, for example, usually omit the rectal examination, with the possible consequence that he may subsequently find that he overlooked an early malignancy of the rectum or prostate? Does he do only a cursory examination because he is overly sensitive rather than realistic about embarrassing the patient?

Hospitalization

Psychological implications. The psychological meaning of hospitalization will vary with the individual patient, depending on his personality structure; the nature, extent, and duration of his illness; and the "character" of the hospital. In any case, the hospital does not always represent a place of refuge and security, where the patient is assured protection from stressful stimuli. Rather, hospital admission is a trying experience for most patients, and especially for those who are involved in a symbiotic relationship with someone at home. Separation anxiety can be intense. The thought of remaining bedfast; the loss of independence, with associated feelings of vulnerability; and the fear of death, however remote, can be extremely stressful. In any event, the reactions to the unconscious meanings of hospitalization can range from feelings of intense fear and anxiety to a sense of euphoria at the prospect of entering a protective, "maternal" atmosphere.

Psychological reactions to the hospital milieu. The hospital is usually, though not always, a relatively strange place for the patient and, as such, requires his adjustment to many new experiences. These may include using bed pans; eating different food at different hours; enduring intubations, immobility, venipunctures, and oxygen tents; watching other patients suffer and die; and, above all, seeing many new faces. Some hospitals are "cold" and "impersonal"; others are "understanding" and "warmly receptive." This will depend primarily on the prevailing attitudes of the staff toward the patients in their care. One way of assessing the variety of experiences which will affect the course of the patient's illness during his hospital stay is to classify them under three broad rubrics, as follows: (1) patient-staff relationships, (2) interpatient relationships, and (3) interstaff relationships. Inasmuch as these relationships will in-

fluence the patient's clinical state favorably or unfavorably, they are of more than passing interest.

Patient-staff relationships. Physicians and nurses are often cast in the role of omnipotent parents. And, concomitantly, if childhood experiences with parents were predominantly unfavorable, either because of excessive frustration or over-indulgence, they may affect current medical relationships adversely. By and large, however, the patient is willing to yield his adult autonomy temporarily and to place himself under the care of the hospital staff.

This commitment by the patient places an obligation upon the physician and the staff. Often, and particularly in public charity hospitals (as opposed to private hospitals), the staff seems to take it for granted that the patient will maintain his attitude of childlike trust and obedience, and he is treated accordingly. It is not surprising, then, that the patient is quite sensitive to the attitudes of the physician and nurse. He is disappointed easily, angered when his expectations are not fulfilled, depressed and apprehensive when the physician or nurse is not available, and responsive to their harsh handling. On the other hand, many patients are so concerned about alienating these people on whom they are so dependent that they stifle their resentments rather than express them and risk disruption of the relationship. The suppression of these intense feelings can have an unfavorable effect on physiological function: It can, for example, precipitate an asthmatic attack, accentuate hypertension, increase the frequency of attacks of angina pectoris, and affect the course of the patient's illness in other ways. Ideally, the patient should be made to feel secure enough to discuss openly his smoldering feelings of anger, fear, and shame.

Interpatient relationships. Patients on wards or in semiprivate rooms and especially those who are hospitalized for prolonged periods of time will, inevitably, be exposed to a variety of meaningful interpatient relationships. These, too, may be beneficial or detrimental. On the positive side, a patient with strong maternal instincts may establish a close relationship with another patient who thrives on such attention, and both may benefit as a result. On the other hand, when both patients in the same room have intense sibling rivalry problems, each may react adversely to any special attention the other may receive from the doctor or nurse. The disruption of a meaningful interpatient relationship as the result of the discharge or death of a fellow patient can be quite stressful. Moreover, the variety of interpatient relationships to which the patient is subjected may influence his already altered physiological functions.

Interstaff relationships. Finally, patients are often sensitive to the relationships among members of the staff. This has been amply demonstrated in hospitalized psychiatric patients; it has become increasingly evident that it is applicable to medical patients as well. For one, unresolved discord between

physician and consultant, resident, or nurse can provoke anxiety in the patient, for he must then cope with his divided loyalties. But, with particular reference to the medical patient, interstaff disagreement may have even more serious consequences: it can reduce the efficiency of patient care and, as a result, impede the patient's progress. To illustrate, a resident who does not support the recommended treatment program of the staff physician may unconsciously rebel against the staff physician's authority by simply neglecting to provide the care prescribed for the patient. A nurse, who is angry at an attending physician for some reason, may unconsciously interfere with his efforts by forgetting to give the patient his medication on schedule. In order to resolve some of these interpersonal difficulties that affect the patient's progress, regular meetings attended by members of the staff, designed to foster open discussion of grievances, are helpful in resolving some of the inevitable interpersonal conflicts between staff members which may affect the patient's progress.

Hospital Discharge

Psychological implications. Paradoxically, many patients experience apprehension when leaving the hospital. Certainly, this seems in contradiction to the atmosphere of smiling faces, warm handshakes, and pleasant "good-byes" which surround the patient as he is whisked out the hospital door. In fact, however, the patient is often unaware of his deeper concern about leaving. Reactions of an emotional or physical variety, or both, may occur. This is especially likely to happen if the patient has been hospitalized for a long time, if his illness was serious, or if there is an ominous threat of reactivation of his physical disorder after he leaves. Or, he may hesitate because of the prospects of facing an unpleasant family, social, or work situation on his return to his former life situation.

Psychological reactions. As a result, prior to discharge, such a patient may experience transient or severe exacerbation of his illness or even develop new physical symptoms. Or he may experience anxiety or other symptoms of emotional turmoil, such as hysterical representations of the symptoms of physical illness. Some patients try to find rationalizations for remaining in the hospital longer. Others overtly express their anger at being "thrown out."

It is not surprising that anyone who has allowed himself to regress to a role of being cared for and protected may find it difficult to give this up. For some patients, latent excessive yearnings to be dependent may be gratified, to some extent, during hospitalization. On the other hand, there are those who abhor such "dependency" and push for discharge much too soon.

Whenever a patient is eligible for discharge, it is important to recognize that these problems may arise. Careful observation can help to explain the develop-

ment or exacerbation of symptoms, when this occurs. The patient can then be encouraged to talk about his feelings about leaving and thereby be helped through this transitional period.

Diagnostic Procedures

In both the hospital setting and within the framework of out-patient treatment, patients must submit to experiences which are strange and unfamiliar and, consequently, perplexing and frightening. Innumerable procedures require the use of strange instruments which cause painful or erotic sensations and are often carried out in weird surroundings by unfamiliar technicians. It is not surprising, then, that patients may fail to appear for office visits when such procedures are scheduled or even sign out of the hospital prior to a dreaded diagnostic procedure. Physicians often forget that, although these medical techniques are a routine part of their daily practice, they can be deeply terrifying for the patient.

Psychological implications. Some diagnostic procedures are genuinely uncomfortable; others are unpleasant because their anticipation arouses certain fantasies. An extremely uncomfortable bone marrow biopsy may be less painful for someone who is familiar with the procedure; on the other hand, an unsophisticated patient may be quite traumatized by a painless electrocardiogram because he expects to be shocked by the gadget which is attached to him by electrodes. A youngster who is afraid of the dark may find even a crude spinal tap less uncomfortable than an upper gastrointestinal x-ray series. In brief, diagnostic procedures will evoke different reactions, depending on the patient's psychological status, the area of the body being studied, and other things. A cystoscopy will be more traumatic for a man with intense castration anxiety than it is for most other patients, and a breast biopsy will be more difficult for a woman with excessive concern about her femininity. On the other hand, diagnostic procedures which must be repeated and cause only mild discomfort can have the opposite effect: the dependent patient who desires a great deal of attention may perceive such procedures as evidence of the physician's interest and care.

In any event, it is important to understand that the patient's response to diagnostic procedures may be psychologically determined, in part. Therefore, it is important that the physician explain the procedure as clearly as possible beforehand. This will not completely eliminate the patient's fears, but it may reduce them, and it will certainly enhance the physician-patient relationship. The physician should also be aware of the fact that patients are usually apprehensive about the outcome of diagnostic procedures and should be informed promptly of the results (to the extent the doctor feels it advisable).

Treatment

Psychological aspects. In large measure, the psychological aspects of the treatment of medical disorders are a function of the physician's relationship with his patient. In fact, this relationship constitutes one of the most powerful therapeutic tools available to the doctor. Yet, unfortunately, this is often overlooked, not only to the detriment of the patient, but also to the detriment of the physician, who may erroneously attribute therapeutic effects to medications or to procedures, rather than his "personal touch" or to the air of optimism and confidence he conveys.

Psychophysiological correlations. Physiological activity is highly responsive to interpersonal relationships. As such, blood pressure, gastric secretions, bowel activity, skin response, and other physiological functions will respond to the physician's subtle and gross communications to his patients. The pharmacological effects of a drug may be enhanced or diminished by the color of the medication, its mode of administration, its size, shape, and taste, and last, but not least, whether or not the prescription is handed to the patient by a warm, smiling physician, or one who is irritable and scowling.

It seems almost trite at this stage in the development of psychosomatic medicine to remind physicians of the need to treat the whole patient, rather than a single diseased organ or a disease process. Furthermore, not only must the patient be treated as a complete organism, but also in his total family and social context, if he is to achieve—and maintain—optimal health. It is useless to heal a patient's peptic ulcer in the hospital and then discharge him only to have it recur because he must again face the very stresses which precipitated the onset of the ulcer.

Chronic Invalidism and Rehabilitation

Psychophysiological correlations. In addition to physical factors, psychological attitudes can spell the difference between rehabilitation and chronic invalidism. Partial or total invalidism is, of course, an inevitable fate for some who have fallen ill, but many patients who are potentially capable of being rehabilitated remain in hospitals because of unrecognized emotional conflicts. In many such instances, rehabilitation will be more successful if the patient can be motivated sufficiently to this end. Recovery from illness involves giving up a somewhat childlike status and regaining the role of adult. The patient's desire to achieve this transition and his success will depend on such factors as his level of maturity prior to the illness, the type of illness, its duration, the extent to which the patient was cared for, his deeper psychological needs, the life situation he faces should he recover, and, finally, the willingness of the staff and others to promote growth in the patient, as opposed to maintaining him in a dependent state. Ex-

perience has shown that patients who were previously considered unmodifiable can respond to a "total push" program of an energetic, interested, and informed staff.

Death

Psychological implications. Everyone is faced with the prospect of eventual death, but illness, and especially hospitalization, may precipitate a more open confrontation with it. At such times, death may be of greater concern to some patients than to others. In any event, since death is a state virtually impossible to conceive of, its meaning must be related to past experiences. In this context, death may be conceived of as an almost welcome relief from torturing pain. Or it may represent a reunion in an afterworld with loved and loving ones. It awakens repressed childhood fears of abandonment in other patients. The suicide patient conceives of death as a justified punishment for his aggressive, destructive impulses. Whatever its psychological implications, when death is imminent, the patient needs a close, trusting relationship to help him face the unknown. Unfortunately, however, because the dying patient often arouses great anxiety among those around him, he is usually neglected or avoided. It is sometimes easier for the physician to walk past the room of the patient who is dying from cancer than to face him and the questions he may pose.

What does one tell the dying patient? Should he be told he will die, if he seems unaware of it consciously? This question is still debated. On the one hand, there is probably some justification for the argument that the patient should not be told, on the grounds that if his hope is completely shattered, any possibility—however remote—of a remission of his illness will be shattered as well. On the other hand, however, there is some evidence that the patient is better able to deal with death if his physician discusses it with him openly. The patient then knows where he stands; he can take care of necessary family and business arrangements; and he can maintain a more open relationship with his family and his physician, who, in turn, will be more comfortable in his dealings with the patient. Still, many patients probably could not withstand such a confrontation. They vigorously deny the obvious, and it is probably best to allow them to continue to do so. Perhaps the best position for the physician to take is that the decision about what and how much to tell the patient should depend upon his psychological evaluation of the person in his care and that the way he handles the matter should be tailored to the specific needs of the individual patient. This would be in contradistinction to establishing a set pattern for handling all dying patients, determined primarily by the psychological needs of the physician.

31.3 PSYCHIATRY AND SURGERY

JAMES L. TITCHENER, M.D.

Introduction

This section will discuss human psychological reactions to surgery, which may range from typical, average, expectable disturbances to profoundly psychopathological disorders. It will include a description of the patient's psychological reaction to every phase of the surgical experience, from the patient's initial discovery of his illness, to diagnosis and the physician's recommendation for surgery, to his hospital admission, to the stressful period he spends in the hospital prior to surgery, to the administration of the anesthesia, to the recovery phase, and, finally, to

the period of convalescence. The section will conclude with a comprehensive summary of the psychological implications of surgery. Consideration will also be given to the physician's possible influence on the psychological processes which affect the surgical patient and the course of his illness.

Psychophysiological interaction. The prospect of undergoing surgery must, inevitably, evoke a psychological reaction in the patient, although the overt expression of that reaction may be stifled or expressed in altered form. In fact, the anxiety, fear, anger, or depression which arises in response to the psychological meaning of the illness, or the operation, or both, can be transformed by the individual's psychic defense system, so that his "public" adjustment to surgery can be quite misleading. Moreover, the possibility of severe and disabling postoperative depression may be greater in a sweetly cooperative patient who is able to repress his fears and anxiety, than it is in a patient who expresses these feelings and, in the process, becomes a difficult management problem.

Whether or not they are expressed, the nature and intensity of the patient's feelings about his illness, hospitalization, and the hazards of surgery may have physiological concomitants which will influence the course of his illness and his recovery from the operation. And this psychophysiological interaction, which is particularly apparent in relation to the surgical experience, can be cumulative. For example, it has been observed that preoperative anxiety about surgery for a duodenal ulcer can deter effective postoperative gastrointestinal function, which, in turn, will give rise to unfavorable emotional reactions which will further impair gastrointestinal function.

Psychological Reactions to Surgery

Regressive reactions. Surgery always causes psychological stress, to varying degrees; in the absence of an ideal adaptive system, this stress causes regression. Simply defined, stress is a stimulus which demands an adaptive response. For a variety of reasons, regression is the most common psychological response to the stress of surgery.

With specific reference to the surgical experience, the phenomenon of regression can be defined as follows. In the face of physical illness, pain, and discomfort, separation from home and family, and admission to a "cold" and alien hospital, where one is confined to bed and left alone to anticipate the prospects of anesthesia and an operation, there is a strong tendency to revert to earlier modes of coping with intangible environmental stresses and the pressures of inner conflict. In some patients, this regression to earlier modes of defense may mobilize personal strengths, but it may also reactivate old fears and conflicts. For example, the patient's unconscious regressive fantasies of going to sleep with the mother

or father anesthetist may ameliorate his fears of anesthesia. On the other hand, however, he may see himself as a helpless child once again, who must submit to a procedure which is unconsciously viewed as punitive.

The manifestations of regression in reaction to surgical stress will differ in individual patients. The regression may be apparent in the patient's thinking or feelings, in his actions, or in his interpersonal relationships. The point is that these modes of emotional expression were adequate and comforting in the past; hence, the patient resorts to them once again, in the face of this current, acute psychological crisis. However, this concept of regression as a chronological phenomenon requires further elaboration: more specifically, the fact that the patient employs modes of thinking and feeling which were appropriate to an earlier stage in his development also implies some decline in ego strength and a resurgence of superego and id forces. Concomitantly, conscious and preconscious secondary thought processes give way to the unconscious primary processes which characterized early levels of psychological functioning. Thus, the surgical patient who has experienced some degree of regression will find it uncommonly difficult to tolerate delay of gratification and frustration, for example, although, as a patient, greater demands may be made on him in this regard. He may be less able to substitute thought for action, and while his need to take action may be limited to a general restlessness or occasional insomnia, it may also provoke a sudden decision to leave the hospital or to advance the date for surgery and "get it over with."

Fantasy production. When the patient's capacity for discharge of feeling through action is blocked, as it usually is while he is in the hospital, the patient's thinking is more likely to be dominated by fantasy. The surgical patient, in particular, may indulge in innumerable fantasies about his doctor, the nurses, his illness, the wound, the operation, the medication, and the anesthesia. This increase in fantasy and imagery, as an aspect of regression, is characteristic even of those patients who are most reality-oriented under normal conditions. It is not necessarily deleterious.

Expression of aggressive and libidinal impulses. As a concomitant of regression, the patient's emotional expressions take on a wishful quality and become less complex or subtle, and aggressive and libidinal components become more apparent. Aggression may be mobilized by the feelings of frustration and helplessness engendered by the illness and the loss of motility. The patient's feelings of helplessness also reactivate certain early libidinal impulses, e.g., passive-receptive wishes and the desire to be cared for.

Interpersonal relationships. As the illness progresses and the day of the operation approaches, regression becomes increasingly apparent in the pa-

tient's typical mode of relating to other people. Thus, to varying degrees, his current relationships with the physician, surgeon, and nurses, as well as his relationships with relatives and friends, will take on the characteristics of his earlier relationships with crucial figures in his environment, such as his parents.

Psychogenesis of regression. The psychogenesis of regression—whether beneficial or deleterious—with specific reference to the surgical experience can be conceptualized as follows.

Quantitative determinants. On the one hand, the regression associated with the surgical experience implies that the patient's adaptive strengths have been quantitatively overcome, and, in this sense, regression may be viewed as a concomitant of a traumatic neurosis. More specifically, the patient's concern and anxiety over his illness and the impending operation tend to exceed his capacity to maintain emotional equilibrium. Thus, individual differences in the severity of regression will depend upon the intensity of the patient's feelings of isolation, immobilization, and the general depletion of his psychological resources, as a result of his fear of injury or death.

Qualitative basis. Regressive phenomena can also be understood in relation to the meaning and content of the stress associated with surgery. That is, from the psychodynamic point of view, the specific meaning of surgery for the individual patient is considered to play a more significant role in the genesis of regression than the quantity of stimuli or stress precipitated by the surgical experience. In fact, the psychogenesis of regression in this patient population can best be understood when both quantitative and qualitative factors are considered in combination. Nevertheless, those who subscribe to this view maintain that regression in the surgical patient is analogous to a transient psychoneurosis rather than a traumatic neurosis.

Within this frame of reference, Deutsch has postulated, on the basis of her psychoanalytic study of surgical patients, that the stress which gives rise to transient psychoneurosis consists of two types of anxiety—narcosis anxiety and castration anxiety.

Narcosis anxiety. By definition, narcosis anxiety refers to the fear of anesthesia. In a broader sense, it encompasses the fear of dying, of not awakening, of separating and slipping away from loved ones, as well as feelings of helplessness, fear of loss of power or control over one's muscles and senses. As such, narcosis anxiety may find many forms of expression. At times, the fear of anesthesia is expressed overtly; at other times, it is displaced onto some other element of the surgical experience. For example, the narcosis anxiety may take the form of a strong aversion for bed rest, or emerge as an insomnia which increases as the day of the operation approaches. In such instances, sleeping medication may be refused or prove ineffective, particularly

when angry feelings about surgery predominate over anxious feelings about the operation. Finally, the patient's repressed fear of anesthesia may emerge as a general, free-floating sense of anxiety which cannot be associated with a specific environmental factor or event.

Even when the patient is consciously aware of his fear of anesthesia and expresses this fear overtly, reactions will continue to be unrealistic and overintense if he is not consciously aware of the emotional significance of this experience, and if he does not fully understand its significance on an emotional level.

A young woman, scheduled to have surgery performed to correct mitral stenosis, was brought down to the operating room three times. On each occasion she had such adverse physiological reactions to the induction of general anesthesia that, finally, surgery had to be postponed indefinitely. In fact, the patient's fear of anesthesia had been evident from the outset and had been expressed overtly. While she was awaiting surgery, the patient had reported repetitive dreams of the actual operation which clearly indicated that there was an unconscious association of administration of the anesthesia to traumatic experiences with angry parents in early childhood. Thus, the patient's fear of anesthesia was intense and overt, but its psychogenesis, the specific psychological determinants which made it excessive to the point where it made the induction of anesthesia impossible for all practical purposes were complex and deeply repressed.

Castration anxiety. According to Freudian theory, "castration anxiety" has its genesis in the young child's typical fear of the loss of genitalia. As a determinant of emotional disturbance and regression in surgical patients, the meaning of castration anxiety may be extended to refer to the fear of injury to, or loss of any body part as a result of surgery. The danger to body parts is, of course, a realistic threat in any surgical procedure. However, this fear may be increased beyond realistic proportions by the reactivation of these early unconscious fantasies, i.e., the child's intense fear that he will be punished for his sexual impulses toward one parent and his aggressive, rivalrous impulses toward the other by the loss of his genitalia.

This phenomenon of emotional association of the fear of bodily damage through surgery and reactivated childhood fears of retaliation from the powerful parent is encountered frequently on surgical wards, but some patients are more likely to manifest this reaction than others. In particular, the stress which is an inevitable concomitant of surgery can be expected to reactivate castration anxiety when these childhood conflicts have not been resolved by the "passing" of the Oedipus complex. The genesis of the anxiety evoked by the revival of these childhood fantasies may be obscured by the mechanisms of repression, displacement, and substitution, but the anxiety itself will be evident in the patient's restlessness; his withdrawn and sullen behavior; his preoccupation with self, or concern about his family at home; his hypochondriacal complaints; his rebellious-

ness and uncooperativeness, or, conversely, his excessive passivity. The castration anxiety underlying these symptomatic manifestations will emerge in his dreams and fantasies or, if these data are not available, it may be uncovered by projective tests.

In summary, the surgical experience is intrinsically stressful. As such, it will inevitably evoke intense feelings, whether these feelings are expressed or repressed. When the patient's previous over-all adaptation has some weakness, a degree of psychological regression is also inevitable from the stress precipitated by surgery. This regression is manifested by alterations in the patient's typical modes of thinking, feeling, behaving, and in the quality of his interpersonal relationships. Considered in combination, the stress, the intensity of feeling, and the ubiquitous regression may be conceptualized as a traumatic neurosis, i.e., as a psychoeconomic event in which the adaptive apparatus is overcome by the sheer quantity of threat or stimuli. But these phenomena can also be understood as a transient psychoneurosis which arises when conflicts leading to narcosis anxiety (i.e., fear of separation) or castration anxiety (i.e., fear of bodily injury) or combinations of both are reactivated.

The psychological consequences of the surgical experience. Whether it is viewed as a traumatic neurosis or a transient psychoneurosis, at least in theory, the regression is entirely and rapidly reversible when the patient's illness has been successfully ameliorated by surgery and the stress is over. In fact, however, the reversibility of regression, like the effects of anoxia on nerve tissue, depends upon the duration and intensity of the regression, and this, in turn, will depend on the adaptive strength the individual brings to the surgical experience. For purposes of this discussion, adaptive strength may be defined as the flexibility, the ego resilience, which enables the individual to cope with the adversities and vicissitudes which are a normal part of life. The individual who can permit some degree of conscious awareness of the anxiety or depression he feels in conjunction with the surgical experience, to the extent that he can accept the fact that he must be confined to bed, his need for care, and the concern of his relatives and friends without feeling too submissive or helpless, has sufficient ego resilience to ensure his recovery from regression once he is no longer under stress.

On the other hand, some patients have a brittle mode of adaptation. That is, the anxiety and depression evoked by the surgical experience are vigorously fought through the defense mechanisms of suppression, repression, denial, or reaction formation. In these patients, the repressed, i.e., nonverbalized, tensions or depressions appear, instead, in the form of disorders of behavior, such as excessive passivity, submission, and feelings of helplessness, or cantankerous rebellion and resistance to treatment. Or the

anxiety appears in masking psychological symptoms. In these cases the patient's adaptation to his illness and to surgery becomes more stressful and difficult. The un verbalized anxiety, for example, may find expression in the patient's increased irritability, in his intensified demands for care, or, conversely, in his adamant rejection of all offers of help. These reactions, in turn, affect the patient's relationships with his doctor and with ward personnel. Thus, the patient's ability to mobilize his defenses so that he can deal effectively with stress is further diminished. Similarly, when depression cannot be verbalized, it will be manifested in apathy, withdrawal, sleeplessness, and somatic complaints, including some increase in psychogenic pain. The patient's essential ability to adjust to medical and surgical routines is thereby diminished.

Brittle defenses such as denial and reaction formation further deplete the resources of the surgical patient who is under stress by their energy-consuming and -bottling up effects. In addition, there is the further danger that these mechanisms may produce a more rapid and profound regression which may deprive the individual of the capacity to mobilize effective defenses against the anxiety and depression which are components of the surgical experience. More specifically, while regression may serve a useful purpose in that it permits the reemergence of an earlier form of adaptation appropriate to being sick, being cared for, and having an operation, when the patient does not have enough energy to control the regressive process to some degree he may become helpless, dependent, and overwhelmed by anxiety or depression. In these patients, anxiety and depression have painful and corrosive effects; they do not serve an adaptive function, i.e., act as a signal to the patient to mobilize his emotional resources. And, not surprisingly, such patients frequently require special help from the surgeon or a consulting psychiatrist in order to avoid severe emotional debilitation as a consequence of the illness and surgery.

Effects of regression on the surgeon-patient relationship. Some reference should be made in this context to the various phases in the patient's relationship with his doctors, particularly the surgeon, and other medical personnel during the surgical experience. The patient's relationship with his doctor is a complex phenomenon which has been discussed at length in medical literature. However, the surgeon-patient relationship may differ in form and content from other doctor-patient relationships. The special aspects of the relationship between doctors and surgical patients are conditioned by the process of psychological regression which accompanies the stress of the illness, hospitalization, and the patient's anticipation of anesthesia and surgery. In particular, the regressive influences on the surgeon-patient relationship stem from the reactivation of problems of trust and autonomy. Erikson has pointed out that one of the

crucial developmental "tasks" of infancy and early childhood is to acquire a sense of trust in the environment and significant persons in the environment, to replace the basic mistrust of the environment and the objects in it. This sense of basic trust comes from "good" experiences with consistent, reliable, and reasonably gratifying parents. The second developmental task is to acquire a sense of autonomy which will withstand basic feelings of shame and doubt. Inevitably, the surgeon-patient relationship, while offering strength and support, will also include a reactivation of conflicts of trust versus mistrust and autonomy versus doubt.

Trust versus mistrust. The patient struggles consciously with the problem of whether he can trust his doctor and nurses at every phase of the surgical experience. And, contrary to general opinion, it is important to remember that this problem has little to do with an objective evaluation of the surgeon's professional competence. Rather, the patient's personal feelings, reactivated from an early period in his development, are at issue, which explains the patient's unusual sensitivity to apparently irrelevant events, because these events have deep meaning in the emotional interaction of surgeon and patient with regard to problems of trust. Consistency in the attitudes of doctors and nurses toward the patient may help significantly to correct possible distortions in the patient's feelings affecting his relationship with the doctor. However, trust is not a matter of logical decision. It is a feeling which derives, for the most part, from forgotten aspects of early child-parent experiences. It follows, then, that the surgeon's ability to empathize with the patient, that is, to emulate the good parent, will prove more effective than a logical, intellectual approach in increasing the patient's confidence in his professional skills.

Autonomy versus doubt. The reactivation of early conflicts involving autonomy may also influence the patient's feelings and attitude toward the surgeon. The bed rest, intravenous fluid, the bed pan, and all the other immobilizing, or dignity-impairing experiences to which the surgical patient is exposed give rise to feelings of impotence, doubt, and inferiority, especially in relation to the doctor. Thus, once again, he must resolve an issue which was of crucial significance when he was a child and under parental control. Specifically, he must rediscover whether it is possible to function independently, as a separate individual, and at the same time accept the essential support of a surgeon (parent) who is considerably more powerful.

Above all, it must be emphasized that these phenomena are not "real" in a logical sense. However, the possible influence of mistrust and haunting self-doubts on the patient-surgeon relationship is certainly real in an emotional sense. Furthermore, although there may be a tendency to do so, the potential effects of these aspects of early parent-child inter-

actions on the current relationship between patient and surgeon should not be minimized. Ideally, the surgeon's response to these primitive needs will be empathic, consistent, and neutral, yet sympathetic. Clearly, the physician should not try to gratify the patient's infantile demands; nor can he react as though the patient's mistrust or self-doubts were justified. Yet he must respond to the emotional reality of the patient's feelings, which means that he must learn to restrain or work through in himself the tendency toward demonstration of anger or impatience which might be warranted in other social interactions.

Delay, polysurgery, and psychosis. There are three psychological reactions to the surgical experience which manifestly interfere with the efficacy of surgical treatment. These are delay in seeking diagnosis and treatment, the tendency to use surgery as a means of dealing with emotional conflict, and psychotic reactions.

Delay. The patient who delays in seeking diagnosis and treatment for an illness requiring surgery is endangering his life or at best prolonging his own discomfort and disability. Yet, such behavior is typical of 30 to 40 per cent of those patients who require surgery. When individuals in this patient category are carefully interviewed, it is evident that the great majority have had some awareness of their illness for a considerable period of time. Usually, they rationalize their failure to consult a physician by claiming ignorance of the significance of their symptoms. In fact, however, such delays must be attributed to psychological factors, rather than a lack of medical sophistication.

Precipitating factors. The psychological mechanism of denial of reality, in this case denial of illness, because it might mean loss of life, loss of livelihood, and separation from one's loved ones is frequently an important determinant of delaying behavior. Denial of illness may occur even in the face of vivid evidence to the contrary, and in such cases the denial must be maintained by exceedingly complex distortions and rationalizations.

Guilt and self-punishment may also motivate delaying behavior. The patient's conscious suffering or the knowledge that his condition is growing worse serves to alleviate his unconscious guilt feelings which stem from unacceptable wishes. Or, again, the patient's delaying tactics, which represent a passive aggression against the self, may serve as a means of gaining love when love is unconsciously associated with suffering and punishment.

Finally, delay in seeking diagnosis and treatment can also be a means of discharging hostility. Although the aim of such behavior would appear, at first glance, to be self-destructive, there is an unconscious secondary goal. The patient's self-inflicted suffering is designed to make the true object of his hostility feel

sorry (and guilty), to the degree that he will join in the patient's suffering.

Polysurgery. The psychological factors which underlie the unconscious attraction to surgery in the "polysurgical addict" are almost mirror images of those which cause other patients to delay surgery. The operation addict who repeatedly presents puzzling symptoms requiring abdominal exploration or last resort elective procedures to resolve ill-defined symptoms and those few patients whose symptoms can imitate acute illnesses requiring emergency surgery may also be motivated by guilt, by self-punitive means of gaining love, and by the need to express hostility by turning upon the self. Additional factors in these cases include strong exhibitionistic impulses, an attraction to martyrdom, or an attempt to resolve psychological conflicts by submitting to an operation for imagined removal of unacceptable feelings.

Psychosis. The recognition of psychosis on a surgical service may be a problem. That is, the excited or agitated forms of psychosis, accompanied by a thinking disorder, are easily recognized, of course, but quiet patients with withdrawn depressions, paranoid reactions, and incipient delirious reactions often go unnoticed. Nevertheless, feelings of isolation may precipitate delirium or an acute brain syndrome, and disturbances in the internal management of aggression may lead to paranoid reactions in surgical patients.

Apart from acute brain syndromes, the psychotic depressive reaction is the form of psychosis encountered most frequently on surgical service. In fact, depressive phenomena, ranging in degrees of severity from reactive or situational depression, to a more severe and lasting neurosis, to a psychosis with disabling withdrawal and immobilization, constitute a most formidable problem in surgical practice. The effects of depression can be devastating: depression saps the patient's vitality and energy; it depletes his will to cooperate in the treatment, and it diminishes his desire to exert even the slightest effort to help himself to cope with the stress to which he is exposed. Depression gives rise to an apathy, withdrawal, and hopelessness which, in themselves, appear to have deleterious psychological effects in many cases. Consequently, there is considerable support for the current clinical opinion that patients with existing severely neurotic or psychotic depression should not be subjected to surgery if it can be delayed. There is increasing evidence that postoperative depressions, either neurotic or psychotic, forecast a poor recovery from surgery, recurrence of the original symptoms, or the onset of new physical and psychological symptoms.

Psychological Implications of Specific Surgical Problems

Casting and traction. Advances in orthopedic techniques allow more rapid mobilization and ambulation of the patient after injury or after operation. These

advances have also enabled more complete restoration of function. And this progress in orthopedic surgery has, in turn, greatly reduced the potentially harrowing psychological effects of prolonged immobilization which is a concomitant of casting and elaborate modes of applying traction. These advances have not eliminated the need for casting and traction, however. In many patients, especially older ones, the encasing or suspension of part or all of the body in traction has a psychologically regressive effect.

A healthy young man without clinically noticeable neurosis was involved in a traffic accident and as a result required plastic surgery and extensive repair of a shattered femur. The surgery was followed by prolonged traction. To relatives and friends, he seemed especially cheerful and courageous during this ordeal. To the professional observer, however, the anxiety precipitated by his immobilization was evident in some of his humor, in the urgent press of speech over many weeks' time, and in the increased sensitivity he manifested in his relationships with others. Thus, he complained that visitors "would not talk to me," although, in fact, his stream of speech did not allow interruption. Minimal psychotherapy alleviated his tension.

The basis for the anxiety which is a frequent phenomenon among patients in casts or traction apparatus is their feeling of helplessness, which is enforced by immobilization. Actually, they are helpless in traction, and this helplessness gives rise to a different, more regressed mode of adaptation. For example, the patient in traction for the fracture of a cervical vertebra is, in a sense, helpless for the duration of treatment, but his adaptive response to the situation will decrease or exaggerate this feeling of helplessness. It may increase if he is pessimistic about the success of the treatment, if he denies that it is necessary, or if he generalizes the body immobilization, so that he feels that his thinking and emotions are stifled too. The dreams and fantasies of a patient capable of an affective response to the stress will demonstrate a preoccupation with dancing, climbing, running, or making love. On the other hand, the dreams and fantasies of the patient who finds it difficult to adjust to his situation will display a preoccupation with themes of isolation and desertion, and a lack of daring in aggressive expression, or even a lack of movement. One may speculate that patients who, prior to surgery or injury, had conflicts surrounding aggression find it more difficult to adjust to the immobilizing cast or traction because the imagined punishment appears to fit the imagined crime.

Eye surgery. It is interesting to observe that children who have had eye surgery and have spent several days with their eyes bandaged frequently refuse to open their eyes immediately and look at the world when the bandages are off, though they complained bitterly while they were on. Furthermore, this behavior is typical even if the bandages are removed in a dark room and even after they have peeped and know that the light will not hurt. A possible explana-

tion of this phenomenon may help us to understand the psychological implications of eye surgery.

Some psychiatric research recently has been directed toward sensory deprivation and isolation experiments. In fact, naturally occurring isolation experiments, involving the reduction of sensory input, have been conducted on eye surgery wards for many years. The eye patient who is deprived of sensory stimuli suffers an upset in ego balance similar to that described in psychiatric reports of such research. With the onset of the temporary blindness and the cutting off of visual experience, there is a shift toward increasing imagery from within. Children do not want to have their bandages removed because they have been able to establish a new balance. They do not want to disturb it once again by a flood of visual stimuli.

For some patients, the isolation which accompanies temporary blindness is a pleasurable, novel experience; others find it very disconcerting. However, if the patient has been adequately prepared for the effects of sensory reduction, they can be less disconcerting. First, loss of vision means an immediate and inevitable decrease in the patient's sense of mastery over his environment. The permanently blind person will ultimately adapt to this situation by increasing the power of other senses and other functions. The patient who is blind temporarily will have to engage in the same struggle for as long as he must remain incapacitated.

A little girl who was just learning to talk had eye surgery which required that her eyes remain bandaged for 5 days following the operation. She became sullen and irritable and even refused to communicate with her mother. The gift which finally broke through the barrier was a talking telephone with a little girl's voice which spoke friendly sentences when the telephone was dialed. It seems reasonable to attribute the success of the gift to the fact that it enabled the child to regain her sense of mastery, at least to some degree. She could make the girl in the phone talk; she could then respond to it and to others.

Gynecology and urology. The psychological implications of urological and gynecological disorders are discussed in detail elsewhere in this volume. Research findings on the psychophysiology of the menstrual cycle reported by Benedek and others constitute the basis for the understanding of the psychological implications of gynecological surgery. It has become increasingly evident that knowledge of the interplay between menstrual dysfunction and feminine psychology should be a part of every gynecologist's armamentarium, and, of course, these psychophysiological mechanisms should be well understood by the psychiatric consultant. Most often, complaints of menstrual dysfunction will not be successfully treated or even diagnosed accurately if the physician does not investigate the influence of mood and psychic conflict on menstrual function and, conversely, the effect of normal and abnormal menstrual function and endocrine balance on mood and con-

flict. It is generally recognized that dysmenorrhea, amenorrhea, and menometrorrhagia are often physiological concomitants of deep emotional conflicts and that these conditions occur in women who have not acquired adequate psychological defenses against these conflicts.

With reference to gynecological surgery, the effects of hysterectomy and ovariectomy on the woman's psychological functioning are deep and pervasive. The comment of a patient several months after a hysterectomy that she felt like "a shell of a woman" tells us a great deal about the psychological effects of the operation. Although her observation may seem rather trite, it is psychologically valid: in the female, apart from their significance for childbearing, intactness of the body and the capacity to reproduce are the unconscious symbols of femininity and womanhood and, hence, the bases for self-esteem. Every patient who has had a hysterectomy will experience some problem on this score as a reaction to the operation. Therefore, this procedure would certainly seem to warrant preventive psychotherapy.

The clinical observer on a urological service cannot fail to be impressed by the prevalence and intensity of pain as a pre- and postoperative complaint in the male patients. Undoubtedly, this phenomenon can be attributed to the sensitivity of the anatomical structures being treated, but another explanation suggests itself: specifically, the pain may be an expression of rage over the threat of castration by urological surgery. The rage is defensively transformed into submissive masochistic suffering, permitting a more acceptable expression of anger. Put another way, the fear of castration, which looms as a particularly realistic possibility in urological surgery, stimulates the patient's anger at the doctor, which enhances his anxiety because it makes the threat even more real. As a defense against this anxiety, the patient turns his anger inward and suffers it in the form of increased pain. This hypothesis is supported by clinical evidence that suppressed or repressed anger often increases pain sensitivity. This hypothesis further suggests that psychotherapeutic measures might be helpful in decreasing pain sensitivity, which is a major problem in urological surgery.

Plastic surgery. Two categories of psychological problems influence the patient's attitudes and reactions to plastic surgery.

Reparative surgery. The first, and most important, group of problems occurs as a consequence of time-consuming multistage reparative procedures following destructive injuries and burns. The feelings of discouragement, hopelessness, shame, and self-loathing which can accumulate during this period while the patient must endure painstaking rebuilding of his face or some other area of his body should be carefully diagnosed and treated lest such reactions undermine the effects of surgery. However, the fact that the treatments are encouraging and results are visible

operates in the patient's favor. Presumably, if the patient's endurance can be strengthened, these unfavorable reactions can be reduced to a minimum.

Cosmetic surgery. The second type of problem, which has been dealt with more frequently in the literature, is the neurotic distortion and unrealistic expectations which bring some people to the plastic surgeon for repair or remodeling of imagined or, at least, exaggerated defects in their self-image. The decision to have cosmetic surgery may stem from several motives, some of which may seem contradictory, although actually they are not. In any event, in each case the decision is indicative of a deep psychic conflict.

When the individual's motives are primarily narcissistic, he is convinced at an unconscious level, although this conviction may be conscious at times, that if he didn't have the kind of nose, mouth, or chin he has, everybody would love him. Another motive is associated with castration anxiety. In these cases, the individual unconsciously equates the body part to be operated on with the sexual organ. In applying for plastic surgery, such an individual may be unconsciously pleading with the omnipotent father (surgeon) to restore a defective phallus, or he may be asking to be allowed to sacrifice a little part of his phallus in order to protect the whole.

The fantasies described here in oversimplified form are elaborated and disguised in some patients who seek surgery. They merit investigation, for the consequences of surgery may be disturbing if it was motivated by unrealistic fantasies which were wrecked by the real operation, in which event the patient's isolating defenses may be rendered useless. Because of these considerations, today plastic surgeons ask for a psychiatric consultation when they suspect that their prospective patient may be motivated by a neurotic distortion of his self-image.

Amputation. A brief case report may serve as a useful preamble to consideration of the psychological implications of amputation.

A middle-aged woman had a mid-thigh amputation. In keeping with her religion and the custom in the rural North Carolina town in which she was born, the limb was buried. Later, during a visit, she begged a relative to disinter the limb and uncross the second toe from the big one because the position was causing great pain. He did and the pain was gone.

Perception of a phantom limb and a wide range of accompanying sensations are almost universal phenomena following amputation, although patients rarely report such experiences spontaneously, probably because they wish to avoid embarrassment and would rather deny the sensations. These phenomena can be explained by neurological and psychological factors. The neurophysiological explanation refers to the integration of spinal neural levels with cerebral levels which maintain the postural model of the body. These concepts border on the mental image of the body, which is formed and modified by experi-

ence. With amputation, the postural model fades slowly (perhaps never); the image of the missing body part is defended by the individual's deep need to maintain an integrated body image. Pain in the phantom limb, then, represents the patient's grief and mourning over the lost body part.

When it begins to fade, the phantom seems to "telescope," that is, the percept of distal parts, which are sensed most vividly, moves slowly inward toward the stump until the toes or fingers remain closely attached to the stump. Treatment is necessary only if there are unpleasant symptomatic manifestations, that is, when pain becomes a problem.

Colostomy. Somewhat related to the phantom phenomenon because it is central to the problem of body image and self-image is the patient's reaction to colostomy.

The colostomy requires a reworking of the patient's feelings about himself and his body, specifically with regard to the control of bowel and bladder function, and the correction of attitudes toward self and the relationship between filth and sin. It is generally recognized that in the child the acquisition of bowel and bladder control is associated with the mastery of aggressive impulses and motility. The outcome of this early learning and the way in which these learned patterns are connected with other aspects of personality formation and functioning will determine the degree to which a colostomy will demand a modification of basic personality structures. In any event, only very rarely will the patient avoid all conflict and emotional discomfort about his colostomy as he learns to deal with the practical problems of control. These feelings of discomfort will be further stimulated by occasional odors and uncontrollable noises and the reaction to these events by other people. This process of relearning can be facilitated by psychotherapy. Colostomy clubs, whose membership consists solely of colostomy patients who face similar dilemmas, may provide considerable support and understanding during the relearning period.

Surgical Outcome and Treatment Possibilities

The concept of vital balance. Menninger has suggested that we consider human problems in terms of a vital balance. More specifically, ego resources and capacities should be evaluated in relation to the support the patient receives from his family, his success in social adjustment, and other strengths. These factors should then be balanced against the ego's integrative task and the stress imposed by forces within or outside of the organism. This idea is eminently applicable to the surgical patient at the end of his recovery and convalescence. The success of surgery will vary, depending on the patient's capacity to resume his former personal, vocational, and social activities. Thus, when the outcome of surgery is considered in terms of this vital balance,

the operation would be considered a success if the patient's previous symptoms have been alleviated and he has sustained no lasting detrimental change in the effectiveness of his modes of coping with emotional conflict and social adjustment. On the other hand, surgical treatment may have left the patient with difficult emotional, social, and vocational problems; or the stress of an otherwise successful operative treatment may have depleted psychological resources so that the balance regarding personal, social, and vocational tasks is less effective than it was previously. These are but three of the possible variations in vital balance in the surgical patient at the end of his convalescence. In brief, the true outcome of the surgical experience should be evaluated in light of the total effectiveness of the patient's functioning after his illness has ended. Its total effectiveness will depend on his vital balance, which will depend, in turn, on the interaction of factors arising from his psychological and physiological adaptation to the illness, the operation, the recovery, and the convalescence.

Maintenance of the vital balance. The maintenance or improvement of the vital balance of patients undergoing the successive phases of the surgical experience is the combined responsibility of the surgeon, the anesthetist, and the general physician, often in collaboration with a consulting or liaison psychiatrist. Ideally, four variables act to facilitate and implement their diagnosis and therapeutic response to the emotional changes in surgical patients when the inevitable stress gives rise to psychological regression and the reactivation of early conflicts. First, they are aware of the high frequency of temporary emotional disturbances as a concomitant of the surgical experience. Second, these physicians possess a practical empathic understanding, the capacity to know what the patient is feeling and the intensity of these feelings. This is not a mysterious gift; it derives from a developed and practiced ability to perceive the patient's feelings from his words, intonation, facial expression, rate and volume of speech, and bodily movement and posture. Third, they have the ability to develop a relationship with the patient and to use that relationship in the patient's best interests. Finally, they can impart their knowledge of the patient to other members of the therapeutic team, i.e., other doctors, nurses, and attendants, who can then contribute to the patient's progress.

If the surgeon knows from experience and training what to expect in general, he can apply this knowledge through practical empathic understanding to the thoughts, feelings, and behavior of the individual patient. The same capacity permits him to decide when to limit the patient's feelings or behavior, when to call for expression of feeling, when to defer treatment, when to reassure the patient or increase information giving, and when to share his observations of the patient's feelings or behavior

with the patient himself. All of this depends on a constructive surgeon-patient relationship and a supportive emotional milieu provided by the coordinated efforts of the entire staff on the surgical ward.

Suggested Cross References

For an alternate viewpoint about the dynamics of reaction to stress, see Section 28.1 on gross stress reaction. Sensory deprivation is further discussed in Section 5.5 under the rubric of experimental psychopathology. For more information regarding the psychodynamics of gynecological disorders see Section 30.8.

31.4 PSYCHIATRY AND DENTISTRY

SOL J. EWEN, D.D.S.

The dental patient brings to the treatment situation not only his rational realistic needs for dental care, but a wide range of feelings related to dentistry—conscious and unconscious, realistic and unrealistic, rational and irrational. Inevitably, he will manifest certain attitudes toward dental pain and toward the dentist as well. And these attitudes, in turn, will reflect vague but powerful feelings of fear and anxiety, and prejudice toward figures in authority.

Furthermore, while the dental patient will, of course, present oral pathology which is due primarily to constitutional, local, and systemic factors, in all probability, the health of his teeth and their surrounding and supporting structures has been profoundly affected by psychological factors. Consequently, all too frequently, the local care of dental caries, of periodontal disease, of leukoplakia, and even of lichen planus does not eliminate these conditions. Indeed, suggestive evidence that emotional factors play a large role in oral dystrophies has been substantiated by research investigations. In this section an attempt will be made to explore and describe the psychological and physiological elements operative in the dental patient which relate to, initiate, or follow in the wake of dental disease.

Psychophysiological Mechanisms

Emotional factors may play a determining or provocative role in the alteration of normal physiological processes, such as salivary flow, endocrine function, resistance to infection, circulation, and other vegetative responses which, in turn, lead to oral pathology.

Salivary flow. Both laboratory and clinical studies have shown that patients with acute anxiety develop a dry mouth (i.e., salivary flow is meager or slow), and, concurrently, the tongue tends to stick to the roof of the mouth, the lips become dry, swallowing is difficult, and the taste buds lose their ability to distinguish food tastes accurately. Concomitantly, it has been shown that the rate of dental decay increases when salivary flow is sparse over long periods of time.

Other authors have correlated psychological dysfunction with increased salivary flow. More specifically, Finesinger and Sutherland postulated that emotional upset leads to increased salivation, and inhibition of affect produces a decreased salivary flow. There is ample evidence to corroborate this hypothesis. In cases of cerebral palsy, tonic impulses overflow into the autonomic nervous system, producing excessive salivary flow and a constant drooling, accompanied by uninhibited, uncontrolled tooth grinding. Again, even after they have been anesthetized, patients who are having their teeth prepared for fillings often release a 5- to 6-inch stream of saliva from the sublingual glands as evidence of tension.

Endocrine dysfunction. Estrogen is prescribed in small doses by gynecologists as postmenopausal therapy to maintain tissue tone and simultaneously evoke a healthier emotional status in their patients. The low production of this hormone is often associated with the gingivitis which accompanies amenorrhea in early adolescence. Thus, in this context, both gingivitis and amenorrhea may be attributed to endocrine dysfunction. More specifically, several authors have attributed amenorrhea to emotional conflict, which may affect pituitary gland function via the sympathetic nervous system and the hypothalamus. Since the pituitary gland controls cellular metabo-

lism, such conflicts may also alter carbohydrate metabolism and calcium metabolism. These metabolic changes affect mouth tissues, and this, in turn, induces gingivitis.

Resistance to infection. Patients who are acutely disturbed emotionally frequently show marked increases in gingival bleeding, ulceration, and salivation, with a marked tendency to soft tissue infection. This observation has been confirmed by research investigations, such as the study undertaken by Moulton, who concluded that emotional depression tends to decrease the body's defense against infection by decreasing the flow of antibodies in the blood stream, thereby facilitating bacterial infection. Thus, with specific reference to oral symptomatology, Schluger observed that the incidence of Vincent's infection reached epidemic proportions in a group of soldiers who were under extreme stress, nervous, and fatigued, and that the high incidence of the infection was due to these emotional factors, rather than transmission by direct contact. Other studies have supported this hypothesis concerning the relationship between necrotizing gingivitis and emotional upset. On the basis of these findings, it can be speculated that depressed patients tend to eat soft foods, which are easy to chew and swallow and might be described as emotionally comforting, rather than foods which are fibrous and coarse. However, this diet leaves the gingiva soft, pale, edematous, and vulnerable to infection by the flora of the host's mouth.

Circulation. Circulation is controlled by the autonomic nervous system. Thus, the patient who is anxious or tense may become flushed, and, in addition, his gingiva may feel full and bleed easily on instrumentation. In contrast, the depressed patient does not develop gingival bleeding, and the tissues remain pale, bluish, and edematous. Positive concern with self will manifest itself in regular active brushing and gingival stimulation and exercise. And once circulation is stimulated, the tissues will become firm, pink, and keratinized once again.

Chewing and swallowing. The function of chewing is learned by imitation of the dominant parent. Moreover, it is voluntary and, therefore, cannot be classified as an unconscious process. However, the terminal phase of swallowing, when the bolus strikes the rear of the soft palate, is performed involuntarily. And at this point the clinical manifestations of tension may find expression in globus hystericus, or the inability to swallow certain types of bulky or coarse foods. On the other hand, the patient may have a regurgitative response, so that masticated food is expelled involuntarily, leaving enough remnants to produce dental decay or sensitivity at the necks of his teeth. Gagging, which is a common physiological expulsive response to oral irritants, may have underlying emotional components. Psychiatric studies have shown that, in essence, gagging is the unconscious expression of aggression or hostility. While, on the surface, it is

an attempt to rid the body of repulsive or disgusting substances, specific aggressive fantasies or recurrent thoughts typically accompany the inability to retain food boli and give rise to gagging.

Physiological concomitants of psychological disturbance

Dental caries. Dental caries is undoubtedly due primarily to carbohydrate intake, together with susceptibility to bacteria. However, emotional factors may play an important role in the etiology of this condition, as illustrated by the following clinical example.

An Indian student, enrolled in the doctoral program of a leading law school in a large city in the United States, began to develop peculiar eating habits as a reaction to the stress of adapting to a new and alien environment and excessive scholastic demands. Moreover, his diet continued to reflect his increasing anxiety and sense of isolation, so that it was soon restricted to sugar-sweetened black coffee, doughnuts, and soft pulpy foods, eaten at irregular intervals. Within an 8-month period, rampant decay had set in, superimposed upon an angry looking marginal gingivitis. As soon as the dentist at the University's clinic indicated a personal interest in the patient's realistic problems, his dietary habits changed, and he was able to undergo extensive dental reconstruction. Thus, in this case, while the direct cause of oral pathology was excessive carbohydrate intake, it may be speculated that the patient's pathological eating pattern, in turn, represented a regressive reaction to a stressful situation.

Regressive tendencies are also manifested by other patient categories. For example, the strong complaints of some patients about the sensitivity of their teeth to sweets and thermal changes are quite out of proportion to the minor tooth decay detected by careful examination. Nevertheless, these patients continue to probe with a fingernail or hairpin, almost as though they wanted to prove to themselves, as well as the dentist, that they have a major dental problem. Obviously, such behavior can only be interpreted as an infantile bid for attention. On the other hand, their "pain" is real. For one, the pain threshold of these patients is low enough to register minor environmental changes. Second, the sensitivity of their teeth is enhanced by sucking motions. Recent investigations have demonstrated that rubbing dry filter-paper strips over decayed areas (which simulates sucking on teeth) tends to create a vacuum which pulls the odontoblasts of the pulp out of their normal positions; these changes in position are registered as pain. It has been suggested that this self-engendered pain is precipitated by and reinforces the patient's need to complain and to regress into infantile patterns of behavior.

Other patients continue to chew gum and eat chocolate and other kinds of candy despite the fact that they are well aware that these substances will destroy their teeth. This form of compulsive eating has been interpreted in the psychiatric literature as indicative of the patient's hostility to the outside world,

and as an attempt to alleviate his frustration, particularly his ungratified sexual desires.

Temporomandibular malfunction. Temporomandibular joint syndrome, which was formerly diagnosed as Costen's syndrome complex, has been clarified and redefined as a pathophysiological disturbance usually related to malocclusion of individual teeth or to a specific anlage of personality problems. Such patients suffer from "clicking of the joint," pain on translation into chewing positions, and pain in spasms of the encasing musculature because of neurotic overwork of the joint. The patient usually attributes the onset of the acute temporomandibular disturbance to the fact that he suddenly, and accidentally, opened his mouth very wide to bite a particularly thick sandwich or a large apple. Typically, the acute symptoms of pain, swelling, and impaired function last for 2 weeks.

In some instances, however, patients become wholly absorbed in the joint pain, center all their emotional concern in the situation, and continue to traumatize the joint by making unusual jaw movements or by opening their mouths wide when eating. The self-destructive, masochistic nature of such behavior is readily apparent. As a result, the patient may develop a chronic spasm, so that the jaw is moved to one side in a crippled motion. This perverted motion further aggravates the situation; one must now contend with the problem of treating the "tic." A variety of treatment techniques may be applied in such cases, including muscle relaxants, suggestion, placebos, heat to the part, rest, and, above all, discussion of the emotional factors which precipitated the patient's self-destructive behavior and the consequent aggravation of his condition. Adjustment of the occlusion should be done very cautiously, for varying the bite may serve to further center the patient's attention on his mouth. In that event, an occlusal neurosis may be triggered which is alleviated only with great difficulty.

With specific reference to the psychogenesis of this disturbance, it has been suggested that it represents the displacement of personality problems onto a specific symptom complex. More specifically, sexual dysfunction and oral-aggressive or paranoid personality organization have been cited as common psychic variables in this condition. It follows, then, that psychotherapy is frequently the treatment of choice for temporomandibular joint syndrome.

Periodontal disease. A brief summary of a research project designed to investigate the psychophysiological concomitants of periodontal disease is relevant in this context. The project was initiated by the author, with the collaboration of Ruth Moulton and William Theaman, and carried out at the Columbia University School of Dentistry. Twenty-three patients with periodontal disease of varying degrees of severity were studied; in each case, a consultant dentist took the patient's psychosomatic history; a periodontist established the diagnosis of the gingival

condition; and a psychiatrist interviewed each patient for the underlying dynamics and the personality picture.

The psychosomatic history obtained from each patient was based on the following outline.

- I. *Patient identification*
Name, age, sex, race
Present status (economic and social, occupational)
Family constellation (parents and siblings, marital partner (age) and children)
- II. *Presenting complaint*
Reason for coming to dentist
Patient's description of symptoms (Comment if description of symptoms is bizarre or exaggerated.)
Patient's emotional reaction to symptoms (Is it out of proportion? Is there embarrassment, anger, fear, self-pity, or pleasure in describing complaints?)
- III. *Present illness*
In what other ways (besides those cited above) does patient feel sick? (appetite, digestion, rest of mouth, fatigue, anxiety symptoms—not to be elicited directly)
When did illness start? Constant or recurrent? (Affected by what—e.g., tension, effort, etc.?)
Can onset be related to changes in general life situation?
Any earlier bouts of illness? Related to what?
Similar illness in family or friends?
How is illness affecting patient's life, in general?
What does patient think caused illness?
What are his expectations and/or fears regarding treatment?
- IV. *Developmental history, with special emphasis on the mouth*
Attention should be directed to:
Psychosomatic illnesses or symptoms related to anxiety and emotional conflicts
Emotional and social adjustment at each stage of development
Temporal relationship between significant physical symptoms and the life situation or specific emotional crisis which preceded or coexisted with these
 - A. *Infancy and preschool age*
Birth abnormalities (harelip, cleft palate, etc.)
Feeding (nursing, weaning)
Introduction of solids. (When? Results?)
Speed of eating; enjoyment or lack of it
Food preferences and idiosyncrasies (allergies)
Appetite (anorexia, need to be forced to eat)
Gastrointestinal disturbances (vomiting, colic, weight, bowels, bed wetting—until when?)
Oral habits (Finger-sucking? How much? How long? Nail biting? Teeth grinding? Chewing objects?)
Teeth (Teething early or late? Missing teeth?)
Chewing patterns? Biting excessive?
Extractions or injuries?
Second teeth (When? Unusual in any way?)
Early care of mouth (Age brushing started? Who taught? Reaction?)
Introduction to dentist? (By whom? General reaction to doctors and dentists)
General health (Illnesses and emotional reactions to these)
 - B. *Late childhood and adolescence*
Continuation of childhood oral habits (sucking, nail biting, oral breathing)

- Food habits (amount of food eaten)
Preferred foods, especially sweets
Eating between meals
Dental experiences (orthodonture, replacements, gum condition)
Patient's feelings about his appearance (especially facial. Did he feel awkward, ugly, shy, fearful, sexually unattractive?)
Any marked changes in life situation or feelings with onset of puberty?
- C. *Adulthood*
General health (significant medical history)
Present eating habits (Diet?)
Oral hygiene (Brushing?)
Gums (soft or hard, bleeding, sore, burning)
Salivation (quantity, foul taste?)
Dental experiences and emotional reactions to them:
Extractions, fillings.
Dentures or replacements (When made? Why?)
Previous dentist (Reason for changing?)
Changes in mouth (during pregnancy, menopause, tension)
Oral habits (smoking, chewing, biting objects, grinding, drinking, gagging, spitting, compulsive coughing)
Importance and meaning of mouth to patient

The research findings indicated that gingival bleeding was characteristic in cases of necrotizing gingivitis. In addition, on psychiatric examination these patients manifested strong oral dependency needs and concurrent anxiety. The most outstanding feature was the apparent fact that the disease had been precipitated by acute anxiety. The emotional factors leading up to the sudden outbreak of the infection had gradually gathered impetus over a period of days or weeks and were obviously related to the onset of the acute gingivitis. Most of these patients were also quite anxious and concerned about their condition, but this represented a secondary emotional response to physical illness which was superimposed on the deeper personality problems.

The two youngest patients in the group studied were girls. Both had left home for the first time to look for work, and in both cases, the separation had given rise to feelings of loneliness and anxiety—and concurrent longings for home and mother. Both these patients had developed acute attacks of gingivitis 2 months after they arrived in New York.

In a third patient there was a sudden recurrence of gingivitis 14 months after the original attack when she was dismissed from the social work training program in which she was enrolled. The patient had a strong impulse to return home but decided to stay in New York and take on a new job. Moreover, she had made this decision without discussing it first with her parents. Since this patient had been overprotected by her mother, this act of independence gave rise to a great deal of anxiety.

In four other cases, the precipitating conflict appeared, on superficial examination, to be sexual in nature. However, in one instance, the psychiatric implications of the patient's symptoms later proved more serious. A young man, who was subject to recurrent attacks of gingivitis, also complained that his mouth had a foul odor, which he attributed to the extraction of a wisdom tooth. His complaints had their onset after a traumatic sexual experience; specifically, the patient had been impotent with an older woman. Several months later, when there was still another recurrence of the gingival bleeding and complaints

of mouth odor, the patient also expressed his fear that he might be a homosexual. He was subsequently hospitalized with a diagnosis of paranoid schizophrenia. In light of these developments, the patient's complaint of mouth odor, which had absolutely no foundation in fact, was regarded as a symptom of the incipient psychosis.

Psychological Determinants and Effects of Oral Pathophysiology

The health of the teeth and gingival tissues may be adversely affected by a number of factors, all of which have emotional components.

Diet. The psychological significance of eating as a major source of emotional gratification has been described at length in the psychiatric literature. Thus, according to Ribble, "There is a great deal of pleasure associated with the function of the mouth area of the body. The lips and tongue are well supplied with nerve end organs, highly sensitive to food and drink. The greatest pleasure to the human being during his first year of life comes through this mouth area in the acts of nursing, eating and drinking." However, apart from the fact that it is a direct source of pleasure in later life, as well as infancy, eating may serve to ameliorate frustration, and in this capacity it may have psychopathological implications. The obesity which results from overeating is the visible manifestation of the patient's uncontrolled persistent frustrations and his neurotic attempts to eliminate them.

On the other hand, the patient with acute anxiety may limit his diet to the degree that he develops avitaminosis, or even anorexia. During periods of mourning, the depressed patient may limit himself to liquids or soft pappy foods; and the accumulation of such foods about the teeth over a period of time may initiate gingival softening and bleeding. Again, infantile dietary habits may persist if the patient is fixated at, or regresses to, an earlier stage of development. Typically, such patients select soft, mushy foods and avoid the need for heavy chewing, which is a requirement of the adult diet. However, this pattern of food selection may have serious consequences. For example, the geriatric patient, who "deliberately" loses his dentures so that he may have an excuse to adopt a more satisfying soft diet may soon become moribund.

Food and calcareous deposits. Depressed patients tend to permit food debris, stains, calculus, and bacterial plaque to accumulate over extended periods of time. And these encrusted and entrapped bits of matter result in halitosis, or mouth odor. Extreme self-neglect of this type may suggest self-destructive or masochistic attitudes, engendered by the patient's greatly diminished sense of self-worth.

Oral hygiene. Physical neglect of the mouth—omission of proper brushing, rinsing, and general debridement—is frequently due to feelings of depression or acute anxiety, or may be a general expression of the patient's rebellion against persons in authority, i.e., parents, teachers, physicians, and dentists alike. As mentioned earlier, insofar as dental decay may be

attributed to the patient's deliberate overindulgence in refined carbohydrates, it may represent an unconscious self-destructive act. Viewed from another perspective, however, the failure to assume responsibility for adequate personal care of the mouth is an expression of the oral passivity of the dependent individual. For these patients, the dentist represents a parent surrogate; consequently, his criticism and admonition gratify their desire for attention.

Nevertheless, dental caries, which is particularly prevalent during adolescence, is unattractive cosmetically. Adolescents and young adults are frequently embarrassed and disturbed by their unsightly, discolored teeth, and when the patient is excessively concerned with his personal appearance, this may have an adverse effect on his social adjustment.

In patients between the ages of 18 and 30, poor oral hygiene may result in periodontal disease of a necrotizing type. These patients are usually ashamed of the appearance of their gums, and they may harbor the unconscious conviction that they were contaminated by sexual contact. Again, the reaction is one of depression and melancholia. When the disease follows its usual course of remission and exacerbation, cancer phobia may intrude to the degree that the patient may be so panic-stricken that he is unable to function normally.

The Psychological Significance of Teeth

The particular psychological meaning the patient attaches to his teeth will, of course, directly effect his patterns of oral hygiene.

The prospect of losing a tooth may elicit a healthy emotional reaction in the child who associates this experience with growing up. And when this experience is given a similar interpretation by his parents, the child's sense of well-being and of personal progress will be reinforced. This is a basis for future attitudes of self-worth and, concomitantly, of self-care. In contrast, when the environment is a rejecting one, the child who accidentally breaks or chips a tooth may be strongly admonished or punished by his parent. However, this will not increase his concern with the care and preservation of his teeth. Rather, such a reaction will elicit feelings of guilt, anger, and self-blame, which are the bases of self-destructive future attitudes. Thus, according to psychoanalytic theory, when a child is emotionally insecure, he may dream that he has lost his teeth as an expression of his fear of death, punishment, or castration.

According to the old adage, the loss of a tooth means the "loss of a friend," but for the adult it may also mean the loss of strength, i.e., virility. On the other hand, the neurotic patient may derive a masochistic satisfaction from the extraction of his teeth. More specifically, such patients demonstrate an unconscious need to be punished. In other words, these patients deliberately seek pain in dental treatment for they feel they are getting just what they deserve.

Again, extraction and restoration may be compli-

cated unduly by the patient's atypical psychological reaction to these procedures.

Weiss and English have described a man who had to have six teeth extracted at the same time. The patient became very angry after his teeth were extracted, and he was quite unable to tolerate the bridge which was to serve for the teeth he had lost. The patient's extraction had served to remind him that his father had died of a coronary thrombosis shortly after some dental extractions. More important, this memory had reactivated feelings of guilt, for the father had agreed to undergo oral surgery largely at the patient's insistence. He defended himself against these guilt feelings by a strong sense of identification with his father and, concomitantly, intense feelings of hostility toward the dentist. The patient was able to accept his bridge as an integral part of himself only after he understood and was able to resolve the psychological conflicts surrounding the extraction of his teeth.

Finally, the menopausal woman may regard the loss of the last permanent teeth and the insertion of dentures as the "last straw," so to speak. And this reaction may be followed by withdrawal or chronic invalidism; the patient's depression may be so severe, she may even attempt suicide. Other patients, whose immediate reaction to this experience is not so dramatic, may begin a soft, pappy diet lacking in nutrition, evidence a progressive deterioration, and ultimately develop anorexia.

Oral habits. Oral habits which are common phenomena in childhood, such as thumb sucking and nail biting, may distort dentition and produce malocclusion if they persist beyond the age of 5 or 6. However, only two-finger sucking, and the presence of adenoids when they impede breathing, produce facial and dental deformities. On the other hand, Pearson has observed that parental management which results in the sudden forceful cessation of an oral habit may produce stuttering, antisocial behavior, enuresis, and tongue thrusting.

With respect to the etiology of such oral habits, it has been postulated that inadequate sucking of the nipple, due to the use of nipples with large openings which require little or no effort on the part of the infant, may give rise to a persistent need for oral gratification. Inadequate sucking may also have broader psychological implications for personality development. Thus, Abraham hypothesized that the premature curtailment of breast-feeding in infancy will produce a specific type of adult personality. Typically, these individuals are selfish, jealous, greedy, never satisfied, always discontented, easily offended, and preoccupied with the idea that they have been deprived of their "rights." Sucking time is an equally important variable in the genesis of these oral habits. And, in addition, inadequate sucking time may produce underdeveloped hypotonic oral musculature, poor speech patterns, and an inability to grasp objects properly with the lips.

Thumb sucking. Dentists and psychiatrists have been concerned with the problem of thumb sucking or finger sucking for many years. It has been suggested that finger sucking fulfills a basic sucking need and is

a normal source of oral organic pleasure. It has also been suggested that when thumb sucking persists beyond the age of 4, it may reflect a lack of maternal warmth and attention during the earliest feeding periods. However, as mentioned above, the dangers of strong interference with the habit on the part of one or both parents have been stressed. Such interference may evoke hostility against the parent. The habit may then be overevaluated as an expression of that hostility and, in that event, persists beyond the stage at which it would normally be renounced. Thumb sucking is then used by the child as an avenue of retreat from reality into a world of fantasy, an escape from the unpleasant realities which disturb his sense of well-being.

Various techniques have been recommended for the alleviation of thumbsucking. (1) When sibling rivalry appears to constitute a problem, the child should be encouraged to talk about his feelings toward his siblings. (2) Special care should be taken to make sure that the child is well fed and well nourished. (3) Toys or pacifiers, or rusks, toast crusts, or foods which require heavy chewing should be given to the child as a possible substitute for the thumb at those times of the day when thumb sucking usually takes place. (4) The child who indulges in excessive thumbsucking is usually a lonely child who is frequently left to his own resources. Such children need more contact with their peers, as well as the adults in their environment. In particular, the child should receive special attention at bedtime, to minimize his feelings of isolation, loneliness, and anxiety.

The habit may be discussed openly with older children, and clinical experience has shown that if the dentist or orthodontist has established a sound relationship with his young patient, the child himself may ask for his help in breaking the habit. In such cases, parent education is a vital aspect of the retraining of the patient. Parents must be made to realize that thumb sucking does not involve any moral issue and that, above all, the child should not be punished for the habit.

Nail biting may follow the curtailment of thumb sucking. It has been speculated that nail biting expresses not only the need to persist in finger sucking, but also the child's feeling of hatred for the parent who has forbidden the finger habit.

In the adult, persistent biting of a pipe stem, constant candy sucking or gum chewing, and even mustache twirling have been cited as extensions of the thumb sucking of childhood. In other words, these habits might be described as socially acceptable means of gratifying the infantile sucking needs which have persisted in the adult. Viewed in this light, one can better appreciate the difficulties involved in giving up smoking. For the addiction to tobacco has deep psychological roots, namely, the patient's strong impulse to gratify his unconscious oral needs. It becomes equally apparent that these patients can rarely break such persistent oral habits by conscious will

power, no matter how sincere and conscientious they may be in their efforts to do so. When these habits may be attributed to distortions in the mother-infant relationship, psychological intervention is usually a prerequisite for their permanent eradication.

Bruxism. Bruxism refers to the habits of clenching, clamping, and grinding the teeth. Tooth grinding is usually a nighttime activity and may be performed in the patient's sleep; clenching and clamping are generally considered to be daytime activities, although they may be conscious or unconscious. The persistence of these oral habits imposes excessive stress on the gingivas and their encasing bone, producing swelling, fibrosis, and improper soft tissue architecture. In addition, this may have a resorbent effect on the underlying bone, leaving the necks of the teeth exposed. A number of contributions to the psychiatric literature have dealt specifically with the psychogenesis of tooth grinding. It has been speculated that grinding represents the unconscious expression of repressed aggression and rage. Furthermore, clinical studies have shown that at times this aggression and rage are so intense that some patients almost push their teeth out of their sockets. In accordance with this hypothesis, the etiological climate which produces this organ neurosis is established in early childhood when excessive moral restrictions prohibit any expression of hostility or anger on the part of the child.

The success of the dentist's efforts to reconstruct the mouth of such a patient will require the patient's insight into the emotional factors which have produced the habit and also the removal of these factors. In the meantime, the dentist can only provide the patient with a thin plastic protector to cover the biting surfaces of the teeth which the patient can insert in his mouth at night when the habit is most active. Obviously, this device cannot correct the condition; rather, it serves a preventive function in that it postpones the ultimate breakdown of the mouth which is inevitable unless the patient receives psychological help.

Bruxism may appear in modified form as excessive gum chewing, nut cracking, crunching of hard candy, chain smoking, and clenching a pipe stem between the teeth. All of these neurotic manifestations are possible substitutes for tooth grinding. It has been hypothesized that all these habits have as their basis maternal rejection, which may have taken a variety of forms, in early childhood. Similarly, all these habits are directed toward the same goal. They seek to satisfy the unfulfilled needs of infancy by providing immediate, highly satisfactory oral gratification. When the patient's immature habit is intermittent or, more accurately, when it appears and disappears in cyclical fashion, one might speculate that it is triggered by current conflicts which reactivate early feelings of inferiority and rejection.

Psychological reactions to morphological abnormalities. Major disfigurement of the face or

mouth will, inevitably, have a profound emotional effect on the patient. Harelip, cleft palate with accompanying disturbances in speech and swallowing, anodontia (agenetically missing teeth), buck teeth, rabbit bite (underslung mandible), disturbing tooth forms or positions, and tooth discolorations (green stain, black stain, tobacco stain, pitting of the enamel) are commonly encountered in dental practice. The social stigma attached to each of these problems may give rise to serious disturbances in ego functioning and concomitant character disorders. For example, the patient may overcompensate for his physical disfigurement by indulging in impulsive, asocial behavior. The dentist can try to prevent the patient's psychopathological reaction to his affliction by support and reassurance. He can also try to provide more tangible help, namely prosthetic devices and orthodontic appliances.

His efforts will not always be successful, however. In some instances, the wearing of appliances has a positive therapeutic effect, in that the patient feels free of anxiety and even develops a sense of well-being for he now feels accepted as part of his peer group in school or in the community. In brief, in a sense, the patient has had his "face lifted," and in the process he has been transformed into a socially acceptable, and even attractive, person. On the other hand, some young patients consider the wearing of such appliances a further disfigurement; and under such circumstances, their insertion in the mouth is likely to cause great anxiety. Obviously, before initiating treatment, the orthodontist would do well to take a history of the patient which is sufficiently detailed to enable him to assess the patient's attitudes toward the appliances and the long term therapy involved.

It may also be assumed that morphological changes in the mouth which are associated with certain chronic syndromes will have a significant effect on the patient's psychological functioning. These would include the unusual and rather bizarre facial changes which occur with rickets (i.e., quadrilateral form of the head, irregularity of dentition, and hypoplasia or pitting of the tooth enamel); achondroplasia, a disturbance of bone and cartilage formation of genetic origin (i.e., saddle nose, small face, and prognathic mandible, giving the appearance of a pushed in face); acromegaly; Paget's disease; leontiasis ossea; Albers-Schönberg disease; microcephalus; pituitary dwarfism; and muscular dystrophy.

Dental Treatment of the Psychiatric Patient

The phobic patient. Phobias, which are an expression of morbid anxiety, may interfere with the effectiveness of dental treatment. For example, in the dentist's office, the phobic patient may repeatedly express his fear of infection from dental instruments which he is convinced are unclean, frequently demand that the dentist wash his hands, and check the freshness of the towel placed about his neck. The phobic pa-

tient may also express concern that the last patient who sat in the chair left something behind on the arms or seat that might contaminate him and demand that the chair be wiped with a fresh towel. The female phobic patient may fear the taste of blood in her mouth, just as she fears the blood of the menstrual flow; to these patients, all the fluids of their bodies are "dirty," and they frequently engage in elaborate rituals to "cleanse" themselves of normal secretions.

As might be expected, the dental treatment of the phobic patient presents serious problems. It is time-consuming, and their suspicions and innumerable questions may sorely tax the dentist's patience. The dentist should be prepared to refer such a patient for psychiatric help, if his phobic behavior seems to indicate strong paranoid trends, if he is unduly agitated, or if there are other indications that a psychotic breakthrough is imminent.

The hypochondriacal patient. The dental hypochondriac continues to complain of symptoms, pain, discomfort, poor function, to protest that there is "something wrong," in his mouth, despite the fact that repeated, thorough examinations fail to uncover pathophysiological changes in the mouth. However, these patients cannot accept the dentist's reassurance; in fact, nothing can shake their conviction that they will lose their teeth shortly, that the color of their gingiva is conclusive proof that they are very ill.

Hypochondriasis has been ascribed to the deprivation of love during the early crucial years of life. This patient population has also been characterized, in general, as lonely, fearful, unhappy, irritable, and depressed. With respect to his physiological functioning, apart from his complaints about the condition of his mouth, the hypochondriacal patient belches frequently, has fullness after meals, and suffers from general gastrointestinal discomfort for which there is no detectable physical or physiological basis. If the dentist sees such a patient in middle age, when the distress has continued over a considerable period of time and there is intense concern with bodily functions, he is dealing with the syndrome of hypochondriasis. Such a patient requires maximum reassurance and minimal dental care. For, in fact, any reconstructive dentistry, no matter how competent, will be regarded as inadequate by the patient. In fact, the patient may be so pessimistic about the outcome of treatment that he may develop a serious depression, to the point where he may even harbor thoughts of suicide.

The hysterical patient. The expression of a mental conflict which is unacceptable to the conscious mind by means of a physical symptom, such as a paralysis, a tic, or a vague pain which has no detectable physiological basis is not uncommon in psychiatric patients. These hysterical or conversion systems are the unique creations of the patient and, in a sense, are invented by the unconscious for the outward expression of particular repressed psychological material.

Thus, the frustration of deep-seated sexual or inter-

personal needs may underly such somatic complaints as headache, tachycardia, gastritis, and colitis, or the mouth and its parts may be used for such abnormal expression. Nail biting, thumb sucking, chain smoking, and excessive gum chewing may be hysterical expressions of such unfulfilled needs.

The hysterical patient may also complain of vague pains about the mouth which radiate through the tissues in a disparate, confused neurological pattern.

A male patient hospitalized with chronic rheumatoid arthritis involving most joints also complained that he was unable to open his jaws to eat. During the initial interview, the patient also revealed that the inability to move his temporomandibular joints bilaterally had produced anorexia. Radiographs of the condyles revealed no ankylosis, no spur formation, no flattening of the condylar head. Examination by an oral surgeon suggested that the malfunctioning of the joints was attributable to fibrous union of the condylar capsule to the glenoid fossa. The patient was duly prepared for surgery, in order to perform a bilateral condylectomy and thereby free the ramus sufficiently to permit active chewing. As general anesthesia was being induced, the mandible dropped open to reveal soft, flexible tissues. Manual jiggling of the mandible revealed no unusual restriction of movement. After consultation with the hospital's psychiatric staff, the diagnosis was changed accordingly to hysterical closure of the mandible in a patient with a chronic anxiety neurosis.

Hysterical adolescent girls and menopausal women who give a history of frigidity or a complete lack of sexual experience or contact, typically present burning tongue symptoms, and/or flashes of pain in the palate or cheeks. In contrast, the male hysteric rarely presents such symptoms. When he does, however, one usually elicits a history of impotence. Other patients in this category complain of vague dull spots about the mouth, extremes of wetness or dryness (xerostomia), and the inability to swallow (globus hystericus), all of which are without visible somatic bases. By their very nature, the specific psychological factors which precipitate a hysterical reaction present a serious—and frequently insurmountable—obstacle to successful dental treatment. For one, the hysterical patient's fear of pain is so acute as to reach panic proportions. As a result, he will fight the dentist's attempts to insert any type of instrument into his mouth. Secondly, such patients frequently have unconscious fantasies of rape or seduction by the dentist, who may represent an attacking father. Concomitantly, the movements of the dentist's fingers about the mouth may be experienced as erotic and thus may threaten further the hysterical patient.

The Dental Treatment of Children

The role of the mouth in psychosexual development. During infancy, the mouth plays a crucial role for it is the vehicle which enables the infant to fulfill his basic physiological needs and permits his earliest emotional expressions and gratifications. At birth, the fifth and seventh nerves of the mouth are fully developed and prepared to perform the mouth's most important function, the sucking reflex. The infant whose sucking reflex is impaired, either neurologi-

cally, muscularly, or emotionally, may demonstrate the physical or psychological consequences of such impairment at later stages of development.

The infant indulges in three types of oral activity:

(1) nutritional, which includes tasting, chewing, partial digestion, preparing the bolus for swallowing; (2) emotional, i.e., smiling, kissing, crying, spitting, vomiting, and gagging; and (3) intellectual, i.e., nonverbal sound making. Concurrently, during infancy, the facial and perioral musculature develop, determining the ultimate shape and form of the lips, teeth, and affecting mimetic expressions.

The mouth is the first source of sexual gratification. The separateness of the nipple and breast from the infant provide the basis for his first awareness of the separateness of self from the outside world. The proximity of the breast and the warmth of the milk and the skin are his introduction to comfort, love, pleasure, and predictability. On the other hand, absence of the breast, irregularity of feeding, poor feeding, and impatient handling during feeding, individually or in combination, are equated with frustration, anger, anxiety, and insecurity. The active sucking of the infant, the redness of his face, the grasping hand, the sounds of satisfaction, and the sleep which follows have been likened to the adult sex act in all of its components. Through the mouth—the tongue, the developing teeth, the buccal mucosa—the infant reaches out to establish his first relationship with his mother. In this way, the mouth serves as the vehicle for introjective and extrojective acts which clarify the infant's relationship to the world around him. The mouth takes in air, food, and objects which are evaluated on the basis of their size, shape, and taste.

The mother, in turn, can assess the quality of the infant's relationship to her and the world around him from his sucking, lip movements, the sounds he makes, from his salivary output, and gagging reactions. The mother who is unable to interpret these phenomena on a nonverbal, unconscious level and thereby to understand what is happening between her and her infant is unprepared to establish a full active relationship with the infant. Concomitantly, the mother who is preoccupied with her own conflicts, fears, worries, and anxieties may lay the foundation for emotional difficulties in the infant. The infant interprets hasty, inadequate, or careless feeding as evidence of rejection by the mother, and these feelings of rejection, in turn, may give rise to inordinate sucking needs; unfulfilled sucking needs may produce thumb sucking or finger sucking, and, as mentioned earlier, when these oral habits persist, they may ultimately result in deformities in dentition.

In addition to the malocclusion, the infant whose oral needs were not gratified may become the obese adult, or the patient who attaches extraordinary emotional and sexual value to his mouth. Abraham characterized the "oral" personality as demanding, whining, and complaining. Spitting, gagging, mouth ties,

and other typical habits reflect their feelings of disgust, displeasure, and dissatisfaction with their lot in life. For such people, the mouth serves as a medium for the communication of negative attitudes; these are the oral-aggressive and oral-dependent personalities who have remained emotionally fixated at an oral-dental level. Inadequate oral gratification in infancy may produce a tendency toward sadistic lashing out in later life. On a primitive level, the teeth are used for biting; on a more sophisticated level, words are used for verbal attack. The dirty mouth (and discolored teeth) and the lack of regular dental care reflect the masochistic attitudes of the orally deprived personality who, because of his lack of self-esteem and feelings of rejection, continues to seek out self-destructive situations.

Treatment techniques. In view of the crucial role of the mouth in psychosexual development, some degree of psychological insight is clearly a prerequisite for effective dental treatment of the child. Ideally, the child makes his first visit to the dentist between the ages of 2 and 3. This is a training period: the child is learning toilet habits, table manners, and how to dress himself. And because he seeks the love and recognition of his parents, the child goes through this training quite willingly. The first visit to the dentist should be part of this training.

The child should be prepared for his initial visit to the dentist by some discussion at home and by first attempts to teach him to brush his teeth. He may even play "going to the dentist." Kits sold in toy stores which are equipped with dental "tools" made of plastic which resemble the actual instruments in the dentist's office provide a good initial exposure to the treatment situation. When the child arrives at the dentist's office, it may be helpful to permit him to examine the equipment and to "clean" his teeth, so that the dentist's hands, voice, the dental chair, the light, and the mouth mirror and explorer become familiar and are no longer a source of anxiety.

The mother may be present during this first visit. However, only hand instruments should be used, and the simplest procedures performed, even if decay is present. The dental drill should not be employed for fillings until the child is older and can understand just what "making a filling" involves. In all probability, he will reach this stage at the age of 4 or 5. At this time, the dentist should administer an injection slowly, deliberately, and without any pressure, after using a topical anesthetic.

The effects of the anesthesia should be described before the actual symptoms of numbness set in. In fact, the child should be prepared beforehand at all times for the usual sequelae of treatment. Although the mother need not remain in the treatment room after the initial visit, she should be within calling distance. It is quite proper to reward the young patient for being treated. In giving the child a small present, such as a balloon or a plastic toy, the dentist assumes

the role of the good father who gives the child comfort and pleasure, as well as dental treatment. These measures avoid anxiety and help to prepare the child patient for more extensive dental care in the future. More important is the fact that rage and resentment are avoided, and dental "pain" is dealt with in a way designed to engender positive, healthy attitudes. Pedodontic offices which cater exclusively to the child dental patient have an advantage in that the furniture, decor, books, and toys combine to produce a more natural and normal setting for dental treatment.

With the end of infancy and the onset of childhood and adolescence, there is a change in the psychological significance of the oral zone. The growing child willingly accepts the social mores of his parents and attempts to adapt to their social criteria. At this stage, permanent teeth begin to erupt, many teeth are missing, and the new ones seem to be out of line. If the child is accepted warmly and wholeheartedly by his parents, teachers, and peers during this "ugly duckling period," his emotional development will be perfectly satisfactory. If his parents express constant disapproval, if his facial appearance is ridiculed by his peers, the child may regard himself as despicable and useless. And he may begin to regard his mouth and ugly teeth as the chief source of his emotional difficulty. He may then become neglectful of home care and tooth brushing and may even regress to "childish" patterns of dependency. Rampant dental decay and gingivitis may ensue.

The dentist who is aware of the emotional implications of this period for his child patient will encourage regular visits, will form a firm friendship with the patient, and will be fully familiar with his hobbies, sports, interests, and dietary habits. Sugar intake should be discouraged, and the child should be encouraged to eat a balanced diet. He should be rewarded for good oral hygiene, but, above all, the dentist should represent a sympathetic, understanding figure rather than a critical authority. Father substitutes, such as the teacher, the pediatrician, and the dentist can help the child through this awkward period. It is usually wise to postpone orthodontic care, so that the patient need not suffer further embarrassment about wearing metal, banded appliances.

Adolescence is an even more difficult period of adjustment, and once again, dental problems may be intimately related to the emotional problems of the emerging young adult. The adolescent does not yet have all his permanent teeth. Retention of deciduous teeth in this period makes the mouth unsightly and embarrassing and gives rise to feelings of awkwardness, self-consciousness, or anxiety. The adolescent's rapid growth is accompanied by an increase in food intake. Enormous amounts of carbohydrates are ingested, so that the highest incidence of dental caries occurs during this period. Malocclusions, rat-bite, retracted mandible, and missing teeth will, of course, contribute to the adolescent's sense of inadequacy.

In addition, the adolescent brings to the dental treatment situation his fears and concern about nocturnal emission, menstruation, pubic hair, long limbs, and social adjustment. Consequently, if treatment is to be effective, it must reflect the dentist's deep sympathetic understanding of the problems faced by his patient. The patient should be addressed as an adult and his opinions valued seriously, and he should be informed of all the dental work that is necessary. If possible, the patient should be encouraged to work so that he can pay part of his dental fees. The patient's willingness to accept his responsibility indicates an ability to meet adult problems, and the dentist will be associated with his feelings of pride in his accomplishment. Finally, the cosmetic, health-giving, preventive value of dental treatment should be emphasized by the dentist.

The prepsychotic adolescent may present a serious problem in the dental treatment setting. The morose, withdrawn adolescent should be injected with an anesthetic slowly and carefully, and extractions are best done under a local anesthetic in such cases. In fact, general anesthesia is frequently threatening for the adolescent and should be avoided whenever possible. When there is some indication of psychopathology, the adolescent patient should be referred for psychiatric consultation.

The Dental Treatment of Adults

The psychological meaning of the mouth. Psychologically speaking, then, the mouth is related, either directly or symbolically, to the major human instincts and passions. By its function, it preserves; it feels and recognizes through its feelings; it participates in mating; it expresses love, as well as hate and anger, the desire to receive and express pleasure on the one hand, and the wish to injure and to kill, on the other.

The taking of a good dental history may elicit unusual expressions of these emotions and their etiological role in relation to dental dysfunction. Such a history may also permit a fairly accurate prediction of the patient's reaction to treatment.

Psychological reactions to treatment. Most adult patients are afraid of dental treatment, although they are well aware of its importance. The patient brings with him to the dentist's office his reactions to dental pain, to dental care, and to the dentist himself; he brings anxiety and fear and his attitudes toward figures in authority. The anticipation of pain or the removal of a tooth may be felt as an invasion of the patient's integrity or physical wholeness. In other words, the patient's fear of extraction may, in fact, represent his fear of castration, that is, of the loss of a precious sexual part. Consequently, the patient's anxiety with regard to dental treatment may exceed his fear of many other forms of treatment.

The patient's attitude toward the dentist is an ambivalent one in which feelings of fear and hatred

for the attacker coexist with feelings of respect and love for the healer, the "all-knowing father" who can treat tissue breakdown in the mouth and cure it. More specifically, on the one hand, the patient endows the dentist with mystical powers and the ability to ward off and control dental ills. On the other, the patient has feelings of anger and hostility toward the dentist because he causes pain and discomfort and because dental treatment is costly and time-consuming. These feelings are the basis for the patient's attitudes toward dental burs, injections, the sound of steel against teeth, blood and saliva; in each case, they require careful attention and deep understanding by the dentist.

The dental patient whose mouth is decayed feels that he has been betrayed by his own body, and he is outraged that his body should do this to him after he has given it such good care. The emotional end product is anxiety. In the psychologically "normal" patient, the anxiety is short-lived and realistically related to the actual toothache or the pain of treatment. The patient learns from experience that the use of drugs and anesthetics can make treatment brief and tolerable. The patient who required multiple extractions and found that his treatment involved only minimal discomfort because he received an intravenous anesthetic may emerge with comparatively little fear of future dental experience.

The patient who has an abnormal anxiety reaction to dental treatment may consistently procrastinate when he must make a dental appointment, and once the appointment has been made, he may be unable to sleep the night before, arrive late for his appointment, or even faint on his arrival at the dentist's office. Each visit may be an ordeal for the patient. His predominant feelings are resentment and hostility, together with a sense of panic. These feelings are manifested in the physiological reactions commonly associated with anxiety, e.g., sweating, pallor, rapid heart beat, hand tremors, and dry mouth. This anxiety response is the key symptom complex in the dental patient, and it is this emotional pattern which must be understood and resolved by the dentist.

The adult's feelings about the value and meaning of the mouth differ markedly from those of the infant and the child. And his specific reactions to treatment will reflect these feelings. Thus, the patient may feel a sense of helplessness when he is asked to "open wide," which may be attributed to an unconscious fear of sexual attack. Other patients feel that work in the mouth interferes with their breathing; consequently, they harbor the unconscious fear that dental treatment may endanger their lives. The narcissistic patient, who regards his teeth as objects of beauty, may resent any procedure which may disturb the status quo; accordingly, dental treatment is considered to represent a potential threat to his appearance, his vigor, and even his sexual vitality.

Even as he continues to do so, the adult patient

may feel inordinate shame because he has neglected his mouth, and he may hesitate to expose the ugliness of his teeth because he is well aware that they represent his negative attitudes toward himself. As mentioned earlier, such a patient may regard the discomfort or pain which may accompany dental treatment as justified punishment for his biting impulses, his hostility, and his sadistic sexual fantasies.

In summary, then, the adult dental patient with oral pathology of varying degrees of severity may overreact to the degree that he feels his mouth is disintegrating, and that his sense of wholeness and completeness has been disturbed. The discovery that his teeth are loose may so weaken his sense of security that a general regression will begin to take place. The manifestations of this regression may be limited to the dental treatment situation, or they may persist outside the treatment setting. In such patients, childlike responses are substituted for more mature patterns of behavior. Specifically, the patient is totally preoccupied with his own well-being, to the exclusion of everyone else in his environment. In addition, he may become very dependent on the dentist, particularly if treatment extends over a period of time, as it must for dental reconstruction, for example.

Psychodynamics of the Dentist-Patient Relationship

Fear is fundamental to dental treatment. The patient is the recipient of the discomfort, and the dentist is the aggressor, the one who metes out the pain. Yet, despite the fact that he operates under a severe psychological handicap, the dentist must establish a positive, enduring relationship with the patient, which will enable him to treat the patient effectively over a period of months or years.

To establish such a relationship, the dentist must be able to function competently, that is, to make calm judgments and decisions regarding therapy in a climate filled with anxiety. When this anxiety is acute, the dentist must be particularly careful to maintain an objective attitude toward the patient, to observe, listen, and evaluate without becoming "involved" in the patient's neurosis. Nor is the dentist immune from psychological conflicts or distortions in his emotional reactions. In fact, the very nature of his professional duties may give rise to masochistic or guilt feelings. Consequently, it is important that the dentist has some insight into the nature of these conflicts and some understanding of his unconscious needs. For once he has acquired such insight, he can lay them aside and treat the patient calmly, sympathetically, and with minimal pain. Concomitantly, once he is convinced that his own psychological problems are not interfering with treatment, it will be easier for him to accept the fact that he is not personally responsible for the patient's negative reactions to the treatment situation.

The dentist is further handicapped in that he cannot use standard techniques in his effort to establish a "good" relationship with the patient. That is, the dentist should not suggest that there will be no pain; he should not deprecate his patient's reactions; nor should he be oversolicitous. The patient is likely to interpret false reassurance as indicative of the dentist's contempt for him; and the dentist's indifference to his discomfort may be regarded as an expression of his hostility. Instead, the dentist can implement such a relationship by demonstrating his sensitivity to the patient's reactions to the lights, the chair, the towels, the instruments, the telephone interruptions, the dentist's hands, the slightest clumsiness, the condition and position of the headrest, the doctor's gown, and, finally, by his awareness of the patient's tension.

The dentist must divide his attention between the mechanical procedures he must perform and his patient's subjective state, and, actually, the latter represents the more difficult aspect of the work. It is quite impossible to judge the presence of tension and anxiety from the patient's facial expression or his subjective reports. It is much safer to assume that anxiety is an inevitable reaction to dental treatment and proceed from there on. Such an attitude will initiate and enhance the dentist-patient relationship over many years.

THE PSYCHIATRIC SYNDROMES

Chapter 32

Psychiatric Disorders Not in Standard Nomenclature

32.1 UNUSUAL PSYCHIATRIC DISORDERS AND ATYPICAL PSYCHOSES

HEINZ E. LEHMANN, M.D.

At the end of the 19th century, Kraepelin's bold masterstroke cleaved the huge block of functional mental diseases into two well shaped and clearly defined endogenous psychoses: schizophrenia—or, as he called it then, dementia praecox—and manic-depressive psychosis. It soon became apparent that this division accounted indeed for most of the functional psychiatric disorders, but not for all of them. There remained a good number of smaller fragments that had their own characteristics, their specific forms of crystallization that could not be fitted easily into the great dual system. These were the unusual psychiatric syndromes—the rare, the exotic, and the atypical mental disorders.

Like most unusual things, these syndromes are often less important but more dramatic and interesting than the common varieties. Many psychiatrists may never encounter a patient showing some of these syndromes, but a comprehensive presentation of psychiatry must include at least a brief review of these interesting varieties of deviant human behavior.

Classification

The following classification of unusual psychiatric syndromes is proposed: (1) Situation-specific syndromes. Behavioral manifestations that occur only in a certain constellation of environmental conditions that are essential factors in the pathogenesis of the syndrome. (2) Idiopathic syndromes. No special conditions are known to give rise to the syndrome other than a postulated constitutional predisposition and certain hypothesized psychodynamic factors. Under the heading idiopathic, one may further distinguish autonomous and associated phenomena, depending on

whether the observed syndrome presents itself as an isolated phenomenon or as a particular modification of another mental disorder. (3) Culture-bound syndromes. Psychiatric syndromes restricted to specific cultural settings. (4) Atypical psychoses. Psychotic syndromes that seem to belong to a well known diagnostic entity but that also show certain symptomatic features which are difficult to reconcile with the generally accepted typical characteristics of this diagnostic category.

Situation-Specific Syndromes

Ganser's syndrome. The German psychiatrist Ganser published in 1898 a report about patients who showed a peculiar hysterical twilight state characterized by what he called "passing by" or "passing beside the point" (*Vorbeigehen*) whenever they were replying to questions. For example, a 22-year-old steel worker presenting this syndrome was asked how many windows there were in the room—there were two—and he answered, "Three." He was asked his age, and he answered, "Forty-eight." He was asked what time of the day it was—it was noon—and he answered, "About 9 P.M." The most remarkable feature in this psychiatric disorder is this phenomenon of the patient's giving an utterly incorrect and often ridiculous reply, although it is quite clear that he has understood the sense of the question. Furthermore, although these patients, according to the information they give, often appear to be disoriented in time and place, their general behavior usually leaves no doubt that they are alert and not confused in the usual sense; they are capable of comprehending the meaning of questions, and they behave, in areas other than the verbal, like persons who are capable of appreciating their environment.

There has been a good deal of discussion in the literature about the similarity of the speech of these patients to "talking past the point" (*Vorbeireden*), which is most typically a manifestation of negativism in catatonic patients. However, the incorrect answer of the catatonic is the first thing that comes to the pa-

tient's mind; it lacks precision because of defective inhibiting processes of the associative apparatus responsible for the selection of appropriate concepts. On the other hand, a patient with Ganser's syndrome gives the unmistakable impression of selecting purposely—though unconsciously—the wrong answer. In other words, the schizophrenic talks past the point by default, and the patient in a Ganser state talks past the point by design.

Auditory and visual hallucinations, hysterical analgesia, true spatial and temporal disorientation, circumscribed amnesia, and lack of insight may also be associated with the Ganser state. It seems, then, that this syndrome frequently bears the marks of a psychosis. Though many authors agree with Ganser's original diagnosis of a hysterical dissociative state of a special kind, Goldin and MacDonald point out that "all of the cases reported since the early German literature appear to have had some kind of psychosis in addition to the Ganser state."

In the differential diagnosis one must consider schizophrenic thought disorder, epileptic twilight state, toxic-organic confusion, and malingering. In most cases it is not difficult to arrive at the proper diagnosis if one carefully observes and analyzes the patient's symptoms in the context of his premorbid personality make-up and his immediate life situation.

Epidemiology. Ganser's syndrome is a very rare disease and is most frequently observed in prisoners. Wertham referred to the Ganser reaction as a "hysterical pseudostupidity which occurs almost exclusively in jails and in old-fashioned German psychiatric textbooks." The first part of this statement is partly correct, and the second part may be true. Old-fashioned German psychiatric textbooks gave more room to careful psychopathological description and analysis than many modern publications do. Several reports have been justly criticized by reviewers because they were based on incorrect diagnoses and discussed cases that did not truly represent Ganser's syndrome.

Etiology. Ganser's syndrome is a functional psychiatric disorder that occupies a strange intermediate position between psychoneurosis and psychosis and between disease and malingering. It may be thought of as a rare, hysterical manifestation, a dissociative state in which the central phenomenon is the patient's unconscious attempt to mimic the disorganized behavior and thinking of a psychotic patient according to the naive and personal mental image he has of madness. The secondary gain of the patient seems to lie in the fact that he escapes a threatening or frustrating reality by conveying the impression of being insane to the people in his environment.

In almost every case the patient presenting this syndrome finds himself in a confining situation. This may be due to actual imprisonment or, as in the case of the young man mentioned above, due to the voluntarily accepted chemical restraint of an alcoholic who is undergoing disulfiram (Antabuse) treatment or,

as in another case, due to the restrictive anxiety provoked by the threat of impending blindness in a patient with a serious eye disease. The last patient was a quiet, chronic schizophrenic who for years, until the onset of his eye disease, had shown few acute symptoms.

Most authors agree that Ganser's syndrome may occur as an isolated dissociative state or may occasionally be temporarily superimposed on other functional or organic mental diseases. The premorbid personality of the patient is often characterized by certain hysterical features. It has been pointed out that this condition has never been observed in persons of superior intelligence.

Treatment and prognosis. Like most hysterical twilight states, Ganser's syndrome is usually short-lived, and the patient recovers within a few days or weeks. Electroconvulsive treatment has been effectively used in these conditions, but it hardly appears necessary to use such drastic physical approaches. Psychotherapy, tranquilizers, and possibly intravenous injections of amobarbital (Amytal sodium) are usually effective in speeding the patient's recovery. Follow-up therapy of the patient has to be considered, as in any other patient who, under stress, has developed a dissociative state.

Folie à deux (double insanity). *Folie à deux* or *folie communiquée* was first described by Lasègue and Falret in 1877. Double insanity and psychosis of association have been proposed as the equivalent English terms. The disease is characterized by the occurrence of psychotic symptoms that have a common delusional link in two or more persons living in close and intimate association.

De Montyel proposed a division of *folie à deux* into three separate conditions: *folie simultanée*, *folie communiquée*, and *folie imposée*.

Folie simultanée refers to the coincidental appearance of psychotic symptoms in members of a family strongly predisposed to the development of an active psychosis, which happened to occur in them simultaneously, but independently, while they were living together.

Folie communiquée is the term used for the appearance of psychotic manifestations in two closely associated persons who are hereditarily predisposed to psychotic breakdowns but who adopt one or more delusions from each other or from others in their environment and retain them in spite of separation.

Folie imposée refers to the phenomenon most frequently given the name *folie à deux*. Psychotic symptoms—most frequently, delusions—are transmitted from a sick individual to a healthy one, who frequently elaborates on the induced delusions. Sometimes more than one person is affected by such an induced psychosis. *Folie à trois*, *folie à quatre*, and *folie à cinq* have also been observed. Goduco-Agular and Wintrob have recently reported on *folie à famille* affecting seven members of a family in the Philip-

piners. The eldest daughter induced in her sisters, brother, and parents a psychosis that culminated in a state of religious frenzy, during which their aunt was beaten to death.

Lasègue and Falret, who published the first paper on *folie à deux*, summarized their observations in nine conclusions, which in the main are still valid and may be paraphrased as follows:

1. Under ordinary circumstances, psychotic symptoms are not contagious from a psychotic to a healthy or another psychotic person.

2. Such contagion of psychotic symptoms can only occur in exceptional conditions.

3. These conditions are: (a) One individual is the dominant one. He is usually more intelligent than the other and gradually imposes his delusions on the more passive and originally healthy partner. (b) The two individuals have lived a very closely knit existence in the same environment for a long period of time, relatively isolated from the outside. (c) The shared delusion is usually kept within the limits of possibility and may be based on past events or certain common expectations.

4. The observations and conditions relating to this disease are very similar in character wherever they are found.

5. This type of psychosis is found more frequently among women.

6. Heredity may be predisposing cause, particularly where two persons from the same family are concerned.

7. The main therapeutic indication is to separate the two patients, in which case the second one may recover once he is cut off from his source of delusions.

8. The second patient is usually not so deeply affected as the first.

9. In some cases the pressure of the psychotic person may be extended to a third individual or even to more persons in the environment. However, it is usually sufficient to isolate only the actively psychotic person from his sphere of influence.

Epidemiology. *Folie à deux* is a rare condition but common enough for most psychiatrists to encounter one or several examples of it in their own clinical experience. It occurs more frequently in women, but the phenomenon has also been observed in men. It usually flourishes in the soil of poverty and economic distress. The poverty of the individuals involved is probably often the result of their illness rather than a causative factor. There seems to be no cultural barrier to its incidence, and the condition probably occurs in all ethnic and cultural groups.

The borderline between *folie à deux* or induced mental disorder and the collective psychoses, where large groups of people have been infected with irrational behavior, is not clearly defined. The dancing mania that swept through parts of Europe during the 16th century and the more localized sudden epidemics of hysterical behavior—for instance, laughing or

jumping—that even in the present day are frequently observed in institutions such as convents and schools and in small communities throughout the world are examples of it. Other more dangerous mental disorders have affected groups of people in the past—for example, the Salem witch trials and the lycanthropy fears and witch hunting that terrorized Europe during the Middle Ages and were responsible for the death of thousands of people who were suspected of being possessed by some demonic force that turned them into animals and witches. A third type of collective mental disorder is represented by the sudden release of irrational and unusually aggressive behavior. It is observed in lynching or looting mobs when large numbers of people, under the influence of a strong emotion and what may be thought of as the herd instinct, temporarily lose rational and moral control and indulge in violent behavior that is entirely foreign to their normal personalities.

Etiology. All these forms of induced mental disorder are of functional origin. Suggestibility has been proposed as the main operative mechanism. This may well be the case in collective psychoses, induced hysterical behavior, and mob actions. However, in cases of *folie à deux*, other mechanisms seem to be at work. The recipient in the *folie à deux* situation often has a somewhat seclusive and suspicious personality that is more easily classified in the schizoid than in the hysteroid category.

A *sine qua non* condition for the occurrence of *folie à deux* is the close physical association and the intimate emotional bond between the two affected people. The mechanism of identification probably plays a key role. The primary focus of induced psychosis is usually a paranoid or paraphrenic schizophrenic whose special adjustment to the world is characterized not only by his persecutory and grandiose delusions but also by a deeply rooted relationship with another person, who is usually in the dependent position. The recipient or passive partner in this psychotic relationship has much in common with the primarily psychotic partner because of many shared life experiences, common needs and hopes, and, most importantly, his deep emotional rapport with and concern for his partner. In order to relinquish his contact with reality to the extent of sharing the delusions of the other person, it is probably necessary for him to be very restricted in his ability to form emotional relationships with other people. He is then faced with either losing the only person to whom he has been—and perhaps ever will be—very close or joining him in his pathological world in order to avoid this loss. Because of this particular emotional involvement, the *folie à deux* psychosis has been referred to as a transference phenomenon.

Treatment and prognosis. Lasègue and Falret's therapeutic recommendation to separate the affected person from the primary focus and source of his delusions, who is usually a schizophrenic, is still the

first measure to be adopted. In a number of cases the passive partner in the psychotic relationship loses his delusions and regains his unimpaired reality testing after he has been separated for some weeks or months from the actively psychotic partner. The latter has to be treated like any other patient suffering from a functional psychosis, that is, with pharmacotherapy or electroconvulsive treatment. The passive partner may require physical treatment to speed his recovery, or he may recover spontaneously over a period of time. He almost certainly requires psychotherapy to help him work through the loss of the other person and accept the fact that the other one is—and he himself has been—mentally ill. At least one case is on record where the passive partner, after having been paranoid for 25 years, recovered within a year after the death of the active partner in the *folie à deux* relationship.

Unfortunately, the mere separation of the two persons involved in a psychosis of association does not always result in a complete recovery of the passive recipient. Layman and Cohen found only 1 case out of 140 in which separation of the two persons was followed by spontaneous recovery of the passive partner.

In a mother and daughter pair, the daughter was a well educated paranoid schizophrenic, and the mother, who had much less education and was deeply attached to her daughter, had made the delusions of her daughter her own. When the two were separated on two different wards of a mental hospital, the daughter did not recover after insulin coma therapy. The mother did lose her paranoid delusions, but she became so severely depressed that the doctors and nurses treating her began to fear for her life, and she was transferred to the same ward as her daughter. Within a week, she had gained 6 pounds and was happy and active—and she again shared her daughter's delusions. Eventually, mother and daughter were released into the community, where they lived together in the same room, worked together in the same laundry, and continued to share the same paranoid delusions, which had taken on more of a grandiose trend. The only important difference in their behavior was the fact that the two were no longer troublesome in the community and stayed away from all the public agencies they had bothered so much before in the pursuit of their delusional beliefs.

It appears that one can only hope to cure the passive partner of a *folie à deux* relationship if one can provide some compensation for the loss the patient has to accept, not only of the psychodynamic service rendered to him by his pathological projections but, more importantly, for the loss of the person around whom his whole life has centered for years. Projective mechanisms responsible for the formation of delusions can be successfully influenced by physical therapies. However, neither pharmacotherapy nor electroplexy can permanently cover the loss of a key person. Only time, personal working through, psychotherapy, social therapy, and social interaction can deal with it successfully.

Idiopathic Syndromes

Gilles de la Tourette's disease. In 1885, when he was studying under Charcot at the Salpêtrière in Paris,

Gilles de la Tourette published a description of this autonomous syndrome, which was later named after him. The syndrome is sometimes referred to as *tic convulsif* and in the German literature as *mimische Krampfneurose*.

The symptoms begin in childhood, usually in children of school age and before puberty. The patients affected with it exhibit an ever growing repertoire of motor tics that involve not only spasmodic grimacing but also violent stereotyped tics. Spasmodic movements of the upper part of the body finally involve the whole body until the ticlike actions are expressed by hopping, skipping, jumping, grinding of the teeth, and other sudden compulsive motor outbursts that, nevertheless, may involve a certain amount of coordination. What gives this syndrome its specific flavor and is pathognomic for it is the compulsive coprolalia that accompanies the muscular tics. The patients are compelled to utter swear words or obscenities; usually, they repeatedly call out four-letter words. The patient's compulsive and stereotyped coprolalia may be accompanied by compulsive coughing, spitting, blowing, or barking sounds. There may also be echolalia, consisting of the repetition of words or short phrases immediately after the patient has heard them. This strange behavior is exhibited spontaneously and unpredictably by the patient, although it may sometimes be triggered or made worse when the patient is experiencing emotional stress or fatigue.

In the differential diagnosis, chorea minor has to be considered. However, the typical verbal behavior is not present in this illness. Another disorder resembling it has been responsible for a phenomenon which has been referred to as the "jumping Frenchmen of Maine." It was first reported in 1880 and can still be observed in certain parts of eastern North America. It is characterized by compulsive jumping and kicking and by the compulsive repeating of the sounds the affected person has just heard. However, this behavior occurs only as a startle reaction to a sudden loud sound and never spontaneously, as in Gilles de la Tourette's disease. The jumping Frenchmen of Maine were probably suffering from latah, a condition discussed below.

Epidemiology. The syndrome in its typical form is not frequently observed. However, Gilles de la Tourette, in his original article, assembled nine in whom he personally observed the syndrome, although in four of them the diagnosis, according to his own criteria, appears doubtful. Eisenberg, Ascher, and Kanner reported seven cases, and a number of other authors have reported two or more cases; so this disease is probably not quite so rare as is usually assumed. Sometimes there is a family history of tics, and the affected children come mostly from families where all interpersonal relationships were strained and the parents' roles were poorly defined for the child, who was prone to feel anxious, angry, and rejected.

Etiology. Organic pathology of the central nervous system has always been suspected of playing a role in the development of the unusually gross physical symptoms these patients display. However, neurological examination and electroencephalographic (EEG) findings are usually negative, even in full blown syndromes, and autopsies of long standing cases have not revealed any consistent lesions in the brain. It must be assumed, therefore, that Gilles de la Tourette's disease is of functional origin. One may think of it as a peculiar mixture of hysterical and compulsive manifestations. The meaning of the patient's symptoms may be understood as a desperate attempt to draw attention to himself and also as the automatized rage reaction of a rejected child. At the same time the coprolalia is unmistakably anal-libidinal in nature. Strong elements of self-punishment also seem to be expressed in the syndrome.

Treatment and prognosis. Until recently no reliable, effective treatment of the condition was known. The outcome was almost always uniformly poor; the patients showed marked personality deterioration and eventually had to be institutionalized or live as recluses. None of Gilles de la Tourette's original cases developed favorably.

Eisenberg, Ascher, and Kanner had no favorable results with insulin treatment, electroplexy, sedatives, muscle relaxants, reconditioning therapy, and hypnosis, but they reported some modest success with long term supportive psychotherapy for the patient and his family.

One of the new major tranquilizers, haloperidol, a butyrophenone derivative, seems to offer the simplest, most practical, and most effective treatment at the present time. Chapel, Brown, and Jenkins have achieved good control of symptoms with doses of 1 to 6 mg. of haloperidol a day. However, there has not yet been enough time to evaluate the long term effects of such maintenance pharmacotherapy.

Autoscopic phenomena. These autonomous phenomena are, as a rule, not symptomatic of any particular mental disorder. They consist of hallucinatory experiences of the person's own body, which—often only as the face or bust but sometimes as the whole body—is perceived within the person's external visual space as though appearing in a mirror. This specter is usually colorless and transparent, but it is seen clearly, appears suddenly and without warning, and imitates the person's movements. The appearance usually lasts only a few seconds, and in most cases these phantoms—which have been referred to as "dislocated body images"—are seen at dusk. In addition to the visual, there may be hallucinatory perception in the auditory and other modalities. The person usually retains a certain detached insight into the unreality of the experience and reacts emotionally with bewilderment and often with sadness. In schizophrenics, the reaction is one of indifference.

Epidemiology. Autoscopy is a rare phenomenon.

Although there is possibly a certain relation to migraine and epilepsy, there does not appear to be a causal connection between autoscopy and psychosis. Sex, age, heredity, and intelligence do not seem to be significantly related to its occurrence. Some subjects have this experience once in a lifetime, but a few seem to be always close to it. Aristotle wrote about a man who could not go out without seeing his double coming toward him. Goethe gave a vivid description of an autoscopic experience: once while horseback riding as a young man, he saw approaching him another horseman, who turned out to be his double and who disappeared after a few moments. Other famous poets and writers—Shelley, de Maupassant, Edgar Allan Poe, for instance—probably also had autoscopic experiences.

A young woman, during an acute anxiety state, saw herself one afternoon, at a distance of about 50 feet, walk up the steps to the gallery of her house. The apparition disappeared within a few seconds, and there was no repetition of it in the following 10 years. She married and continued to suffer from occasional states of pathological tension, but otherwise she was in good mental health.

A research physicist who enjoys a considerable reputation in his special field of work and who has never needed psychiatric treatment frequently has autoscopic experiences and is rather intrigued by them.

Etiology. The cause of the autoscopic phenomenon, like the cause of other complex hallucinations, is not known. One theory holds that the phenomenon reflects an irritation of areas in the temporoparietal lobes; another holds that it represents the projection of specially elaborated memory traces. Occasionally—but certainly not regularly—the phenomenon is symptomatic of schizophrenia or depression.

Lukinowicz, whose study is the best reference on the subject, thinks that there exists a phenomenological and psychodynamic relation between autoscopy and such parahallucinatory phenomena as imaginary companions, eidetic images, hypnagogic imagery, clairvoyance, and some anatomically incomplete body image disturbances such as phantom limbs. He pointed out that many authors believe some normal subjects with well developed imagination, a visualizer type of personality structure, and narcissistic character traits may occasionally see their double under conditions of emotional stress.

Treatment and prognosis. There is rarely any need for special treatment of this condition, which, in most cases, is neither incapacitating nor progressive. In certain instances, treatment of the accompanying neurological, neurotic, or psychotic condition may be indicated.

Capgras' syndrome. The characteristic feature of this associated phenomenon is the patient's delusional conviction that certain persons in his environment are not their real selves but instead are doubles—in French, *sosies*—who, like impostors, assume the role

of the persons they impersonate and behave like them. This syndrome was first described by the French psychiatrist Capgras in 1923 and has since been discussed in a number of publications in the English psychiatric literature.

Distinctions have been made between the misidentifications of the exuberant manic, the confused amnesic, and the preconceiving delusional patient. Only the last may be diagnosed as cases of Capgras' syndrome. There is also the difference between the positive double—for instance, in the autoscopic phenomenon—and the negative double—as in Capgras' syndrome, where the existence of the double is simply assumed. Sometimes the patient points out that there are certain minute differences between the appearance of the person he considers to be an impersonator and the real person, but in other cases the double has the identical appearance of the real one.

Epidemiology. This is a rare syndrome that occurs more frequently in women than in men. In fact, for some years it was thought that it could not occur in men. Since then, several apparently genuine cases of Capgras' syndrome in men have been reported. No cases are known where the condition definitely did not occur as a manifestation of another psychosis, usually schizophrenia. It has, therefore, been suggested that it may be more appropriate to speak of Capgras' symptom rather than of a syndrome.

Etiology. A necessary condition for the occurrence of this syndrome is the impairment of reality testing that develops only as the result of a psychotic process. Capgras explained the particular nature of this illusion as the result of feelings of strangeness combined with a paranoid tendency to distrust. A disturbed sense of coenesthesia—that is, of the subjective feeling of one's own organism as an integrated unit—has been held responsible for it. Others consider it the expression of an affective disorder. The similarity of the illusion to certain phenomena during the epileptic aura and to false memories of familiarity, such as *déjà vu*, has also been pointed out. It has been explained as a disjunction between the central processes of perception, recognition, and thinking.

The illusion of *sosies* or doubles occurs almost always in the setting of a paranoid psychosis and involves only people who are important and very familiar to the patient. He identifies the appearance of these persons intellectually, but, lacking the fundamental and irreducible feeling of familiarity that is a necessary condition of all true recognition, he does not recognize them and explains their likeness to the familiar person through the delusional postulation of a double.

This uncoupling of normally fused components of perception and recognition may have a neurophysiological cause that so far remains unknown. It may, on the other hand, be determined psychodynamically. Arieti and Meth see Capgras' syndrome as an unusual form of psychotic displacement: the patient rejects the

particular person involved and attributes bad features to him, but he cannot allow himself to become conscious of this rejection because of guilt feelings and ambivalent attitudes. What he really feels about the person with whom he is confronted is displaced to the double, who is an impostor and, therefore, may be safely and righteously rejected. The splitting of a person who constitutes an important libidinal object into his good and bad parts—a basic psychodynamic mechanism—is transduced into perceptual reality by the patient in Capgras' illusion.

Treatment and prognosis. The outcome of this condition depends on the therapeutic success with the psychosis of which it is only an aspect. If it accompanies a periodic affective psychosis, it comes and goes with the phasic occurrence of the disorder. Like other psychotic manifestations, it often responds to electroconvulsive treatment and pharmacotherapy, at least temporally.

A paranoid schizophrenic woman who, 10 years before, had exhibited Capgras' syndrome and could never be convinced of the identity of her husband, who visited her regularly in the hospital, eventually lost her delusions regarding his double following electroconvulsive treatment and pharmacotherapy and was discharged into the community. However, she then felt estranged from her husband and obtained a divorce. Recently, she had to be rehospitalized. She is again mildly paranoid, with a well preserved personality, and shows no trace of Capgras' syndrome.

Clérambault's syndrome. It would be advisable not to perpetuate the existence of this questionable syndrome in the literature. If, nevertheless, it is briefly discussed here, it is because there are references in the French, Italian, Brazilian, and North American psychiatric literature to two entirely different syndromes, both named Clérambault's syndrome, although neither of them seems to deserve the status of a special psychiatric entity. A brief clarification of this confusing situation may serve a useful purpose and possibly hasten the final demise of these two-faced pseudosyndromes.

In 1959 Arieti and Meth described Clérambault's syndrome as *psychose passionelle* or erotomania and cited Balduzzi, who referred to it in the same sense. Arieti and Meth mentioned that this condition—the delusional conviction of a woman that a man who hardly knows her is passionately in love with her—is not rare and in the United States is generally classified as a paranoid condition or paranoid schizophrenia.

But in 1920 Clérambault—according to the Brazilian author Silveira—had started the systematic study of another Clérambault syndrome, on which another Brazilian author, Whitaker, later elaborated. The syndrome to which these authors referred has nothing to do with a patient's passionate infatuation but is characterized by automatism of the mental apparatus, explosive and absurd utterances, thought echoes, and the feeling of being possessed and influenced by some

dissociated force. Clérambault—according to Silveira—explained this phenomenon as a result of a disturbance of the intraneural chronaxia and the superposition of fixed irradiations in two equivalent circuits in the central nervous system. Whitaker later reported on two patients whose psychiatric symptoms were characteristic of Clérambault's possession syndrome and in whom a hypophysodiencephalic disturbance could be demonstrated.

This possession syndrome of Clérambault strongly resembles the experiences of being influenced and directed by an external force, experiences that are frequently expressed by schizophrenic patients, in whom they usually occur in a setting of altered body image, kinesthetic hallucinations, and paranoid delusions. It appears to be quite unnecessary to single out a group of symptoms that are neither rare nor particularly distinctive and that seem to occur in functional as well as in organic disorders of the central nervous system.

Today there is a general tendency in medical terminology to avoid proper names in diagnostic designations as much as possible and to eliminate the artificial singling out of symptom groups that do not clearly exist as independent entities. Therefore, it is suggested that the term "Clérambault's syndrome" no longer be applied to the two different symptom groups that have hitherto gone under this name and that these symptoms in the future be subsumed under the headings of the more general pathological conditions of which they are partial manifestations.

Cotard's syndrome (*Délire de négation*). At the time when most current psychiatric classifications crystallized, during the last 2 decades of the 19th century, the French psychiatrist Cotard described several cases suffering from a syndrome he referred to as *délire de négation*. It has never been possible to see in which way patients with this syndrome differed from those who manifest what psychiatrists usually call nihilistic delusions. Such delusions are by no means uncommon in patients suffering from endogenous depressions, and they also occur in patients with organic brain disease, such as senile psychosis and lesions of the parietal lobe.

It is true that Cotard described patients in whom such nihilistic delusions were particularly intense and all encompassing. Patients exhibiting *délire de négation* complain of having lost not only their possessions, status, and strength but also their heart, their blood, and their intestines. The world beyond them is also reduced to nothingness. Trees, houses, other people do not really exist any more. Time is no longer going on, and, as it has stopped, the patient—by a strange paradox—has become immortal. The full blown syndrome is characterized by this delusion of immortality, which may occur in combination with other megalomaniacal ideas. One woman presented by Capgras and Daumezon with the diagnosis of Cotard's syndrome called herself "Madame Zero" in order to emphasize rather dramatically her nothingness.

Epidemiology. This syndrome is frequently encountered in Western culture by psychiatrists who study their acutely psychotic patients carefully before the psychopathological manifestations have changed or disappeared under the influence of electroconvulsive treatment or pharmacotherapy. The clearly expressed syndrome has been seen most frequently in manic-depressive patients during the depressed phase, but occasionally it occurs in acute schizophrenic breakdowns and in certain brain syndromes.

Treatment and prognosis. In its pure form, the syndrome usually lasts only a few days or weeks, and it responds to any treatment that influences the basic disorder of which it is a part.

Culture-Bound Syndromes

Amok. This is a sudden, unprovoked outburst of wild rage that causes the affected person to run madly about, usually armed with a knife, and to attack and maim or kill indiscriminately all men and animals in his way before he is overpowered or killed himself. This savage homicidal attack is generally preceded by a period of preoccupation, brooding, and mild depression. After the attack, the person feels exhausted and has complete amnesia for it. The Malayan natives also refer to the attack as *mata gelap* (darkened eye).

Epidemiology. The condition is almost exclusively associated with Malayan people, where it occurs only among men, but it has also been reported occasionally in African and other cultures in the tropics.

In Malaya, amok was apparently a fairly common phenomenon a few hundred years ago. It was still frequently seen when the British took over the administration, but its incidence dropped sharply when it was ordered that all amok cases be captured alive and be brought to court. By the 1930's, amok had become a rare condition and, according to Murphy, has today virtually disappeared in Singapore and Malaya and is quite rare in Java.

Etiology. Murphy pointed out that there are three distinct historical phases, during which the nature of amok has changed considerably. In early Malay epics of the 15th century, amok attacks were understood as natural reactions to frustration, provocation, or humiliation to which the person had been exposed. It sometimes served as a mode of suicide if the person found himself faced with an intolerable situation. In that historical period amok was not considered an insane act but was an understandable reaction and accepted by social customs.

With the arrival of Western trade, civilization, and administration, the nature of amok changed. It occurred most frequently in people who were suffering from a chronic physical disease, some gastric trouble, or a painful ulcer. The affected person was often somewhat melancholic for a few days before the attack and later claimed that the devil had entered into him and that he did not remember anything. The amok attack

at that time was no longer a socially condoned reaction but was the result of an acute complete dissociation from the person's consciousness.

The third period dates from the 1920's to the present time. Amok has become a very rare disease, and attacks are now usually associated with an acute toxic condition due to malaria or another febrile condition. Amok is also seen more often in chronic delusional psychoses. In fact, at the present time amok occurs almost exclusively in patients suffering from a serious mental disorder, either a chronic psychotic or an acute confusional state due to a toxic disorder of the central nervous system.

Why this particular form of violent psychopathology has developed only among the Malayan people is not entirely clear. The easy availability of the knife as a lethal weapon has been cited as a contributory factor. It has also been theorized that a culture that imposes heavy restrictions on adolescents and adulthood but allows children free rein to express their aggression may be especially prone to psychopathological reactions of the amok type. Such local customs of child rearing are found among the Javanese, for instance. The belief in magical possession by demons and malignant spirits may be another cultural factor that has contributed to the development of the amok syndrome in the Malayan people.

Treatment and prognosis. Obviously, the only immediate treatment consists of overpowering the amok patient and obtaining complete physical control over him. The attack is usually over within a few hours. Afterward, the patient may require treatment for the toxic confusional or the chronic psychotic condition that was the underlying cause. Murphy reported that, in the old prison-like hospitals before 1918, amok was a common occurrence, whereas, in the new, better staffed hospitals where a more therapeutic atmosphere prevails, amok has all but disappeared.

Koro. This is an acute anxiety reaction characterized by the patient's desperate fear that his penis is shrinking and may disappear into his abdomen, in which case he will die. Since this is a fairly widespread belief in those cultures where the koro syndrome is observed, the patient's family or friends who rush him to the doctor are usually very disturbed about this danger. Almost invariably the affected person has secured a strong physical hold on his penis, sometimes tying a ribbon around it or clamping it into a wooden box.

Epidemiology. The koro syndrome occurs only among the people of the Malay archipelago and among the South Chinese (Cantonese), by whom this reaction is referred to as *suk-yeong*. Corresponding female cases have been described, the affected woman complaining of shrinkage of the vulval labia and the breasts. Occasional cases of a koro syndrome among people belonging to the Western culture have also been reported. Kraepelin in his textbook mentioned shrink-

age of the penis among the hypochondriacal delusions of the depressive states in manic-depressive psychosis.

The typical syndrome is rather rare. Yap recently made a comprehensive survey of the literature on Koro and reported on a series of 19 cases collected by him over the last 15 years.

Etiology. Koro is a psychogenic disorder resulting from the interaction of cultural, social, and psychodynamic factors in specially predisposed personalities. Culturally elaborated fears about nocturnal emission, masturbation, and sexual overindulgence seem to give rise to the condition. Probably all koro patients have been troubled by what they consider sexual excess and by fears about their virility. As precipitating factors in the koro attack, Yap mentions coitus, sudden exposure of the penis to cold water or cold air, and hearing about people dying from koro. He considers koro a unique example of a depersonalization syndrome affecting the integrity of the body image. In contrast to other states of depersonalization, the koro patient's insight into his own condition is usually quite impaired.

Treatment and prognosis. Yap's patients were treated with psychotherapy, tranquilizing drugs, and, in a few cases, modified insulin and electroplexy. On follow-up examination after 1 to 9 years, one third had completely recovered, and about one half had ceased to have further attacks but were still subject to anxiety, and one patient had shown no improvement at all. As with other psychiatric disorders, the prognosis is related to the premorbid personality adjustment.

Latah. This rather spectacular syndrome is also known by many other names. It has been mostly observed among the Malaysian people, and it occurs clinically in two different forms. One is the startle reaction, in which a sudden stimulus provokes the suspension of all normal activity and triggers a set of unusual and inappropriate motor and verbal manifestations, over which the affected person has no voluntary control. The other type of latah is a mimetic or echo reaction, in which a sudden stimulus compels the affected person to imitate any action or words to which he is exposed. In other words, he is exhibiting sustained and complete echopraxia, echolalia, and often automatic obedience. Although the person affected by the latah reaction cannot control or inhibit his peculiar behavior, he remains aware of the situation and may verbally protest against any unacceptable action he is forced to carry out, such as disrobing in public. Since the patient in the latah state is at the mercy of the people in his environment, he may sometimes be the butt of practical jokes.

The latah reaction may consist of a brief exhibition of startle and echo symptoms that, in addition to a startling stimulus, may also occur as a reaction to being suddenly embarrassed or tickled. In this state, the affected person may utter obscenities or ask extremely indiscreet questions. It may become a chronic

disease that, after years, leads to permanent automatic obedience and echo reactions, forcing the affected person into hiding and inducing marked personality deterioration.

Epidemiology. The disorder is found in women of all Malaysian races, especially the Javanese, but it is also observed in a smaller proportion of men in Malaysia. In the 19th century it occurred mainly in men. At that time it was quite common and could be found in all classes of society. Murphy writes that since the 1930's the condition has become rarer and affects almost solely women of middle age and of particular occupations, such as domestic servants. After World War II it became difficult to find any cases of latak in Indonesia. However, conditions similar to and often identical with latak have been reported from other cultures, among Africans, aboriginal Siberians, Laplanders, and North Americans ("the jumping Frenchmen of Maine"), for instance.

Etiology. Yap, who has written a comprehensive review of latak, considers it to be an intense fright reaction involving disorganization of the ego and obliteration of the ego boundaries. He theorized that a sudden fright may provoke inhibition of proper perceptual-motor integration and may, through loosening of the ego boundaries, render the patient powerless to resist any stimuli coming from the environment. As a result, the patient's behavior is determined by echolalia and echopraxia. Yap interpreted the coprolalia that is sometimes observed as a symbolic defensive act.

Murphy discussed the similarities between latak reaction and posthypnotic behavior: there is usually no personality disturbance outside of the attacks, intelligent people are more frequently affected than mentally defective ones, and it may be difficult to get a person out of the state if he is neurotic or hysterical. Murphy also compared the latak reaction and its symptomatic outbursts of agitated behavior and obscenity in otherwise respectable and efficient servants to the erotic and agitated behavior often seen in spinsters undergoing general anesthesia for an operation and to the blasphemies of religious men sometimes uttered under those circumstances.

Although Murphy considers latak a psychogenic disorder, he is reluctant to call it a neurosis. He thinks that the traditional belief of the Malayan people in possession states and their children's games of producing trance states, during which the children behave as though they were animals, and the frankness and absence of disguise for sexual imagery, which is characteristic of Malayan mythology, are cultural factors that may contribute significantly to the specificity of the latak reaction among the Malayan people.

Treatment and prognosis. As with other periodic psychogenic disorders, treatment consists of psychotherapy and pharmacotherapeutic tranquilization. It is probable that behavior therapy would be particularly effective in the latak reaction, although there is

no known record of such treatment having been applied. In those cases where the latak reaction is associated with a chronic mental disorder, pharmacotherapy and electroplexy are indicated.

Piblokto. Occurring among the Eskimos, and sometimes referred to as "arctic hysteria," this condition is characterized by attacks lasting from 1 to 2 hours, during which the patient, who is usually a woman, begins to scream and to tear off and destroy her clothing. While imitating the cry of some animal or bird, she may then throw herself on the snow or run wildly about on the ice, although the temperature may be well below zero. After the attack, the person appears quite normal and usually has amnesia for it. The Eskimos are reluctant to touch any afflicted person during the attack because they think it has something to do with evil spirits.

Piblokto is almost certainly a hysterical state of dissociation. It has become much less frequent than it used to be among the Eskimos.

Wihtigo. Wihtigo psychosis is a psychiatric illness confined to the Cree, Ojibway, and Salteaux Indians of North America. They believe that they may be transformed into a wihtigo, a giant monster that eats human flesh. During times of starvation, a man may develop the delusion that he has been transformed into a wihtigo, and he may actually feel and express a craving for human flesh. Because of the belief in witchcraft and in the possibility of such a transformation, symptoms concerning the alimentary tract—like loss of appetite and nausea from trivial causes—may sometimes cause the patient to become greatly excited for fear of being transformed into a wihtigo. Yap considers this illness a good illustration of the effects of mythology and cultural environment on psychiatric manifestations and thinks that nosologically the disorder may be, like other demoniacal possession states, essentially hysterical in nature.

This particular disorder has probably become extremely rare by now, if it still exists at all.

Voodoo. The possession states associated with the mythology, cultural tradition, and specific rituals of the voodoo belief have been popular subjects for discussion among anthropologists, psychiatrists, writers, and people in general. The voodoo cult, which is practiced in African societies and among the colored West Indians, is particularly widespread in Haiti. A survey of the incidence of psychiatric disorders in that country reveals an increased incidence of hysterical and epileptic disorders. In many cases it has been difficult to determine whether the convulsive manifestations so frequently seen among the Haitian population are due to epilepsy or to hysteria. At a typical voodoo ceremony, dozens of people, after 2 or 3 hours of dancing to the wild rhythm of the drums and under the incantations of the voodoo priest (houngan), fall into hysterical trance states, during which they exhibit convulsions, excitement, the *arc en cercle*, and short twilight states. An outsider briefly has the im-

pression of being projected backward in history and attending one of Charcot's clinical demonstrations at the Salpêtrière.

Aside from these short ritual-induced hysterical states, the psychiatric significance of voodoo lies in the widespread belief of the people of these cultures in the possibility of being possessed by evil spirits. Because of this, chronic, hysterical, and psychosomatic states may be induced, and appropriate treatment for such conditions and for major psychoses due to other causes may be delayed.

The question of voodoo deaths—that is, of the fatal consequences of the patient's belief that he is a victim of black magic and an evil spell cast on him—has still not been definitively clarified from the scientific point of view. Cannon, after having made a thorough search, convinced himself that such deaths had occurred in South America, Africa, Australia, New Zealand, Haiti, and some Pacific islands. He hypothesized that such deaths are the result of a state of shock produced by a sustained level of excess adrenalin in the organism. But Richter, on the basis of experimental observations in rats, suggested that those deaths—if they occur—may be associated with signs of vagal rather than sympathetic overstimulation. He showed that the survival rate under stress was dramatically reduced in wild rats that had been put in a situation that induced a state of hopeless resignation in them. As they succumbed, the ECG recorded distinct slowing of the heart rate; their respirations also slowed, and the body temperature fell. Cholinergic drugs hastened the death of the animals. Finally, Barber doubts the evidence for either theory of sympathetic or parasympathetic voodoo deaths and pointed out that many such magic deaths were due to poison, organic illness, or the victim's refusal of food and water.

Atypical Psychoses

The more closely one studies the psychopathology of an individual psychotic patient, the more frequently one discovers that his condition does not fit easily into one of the existing diagnostic categories. Some subdivisions of schizophrenia have not yet been incorporated into the official classification by the American Psychiatric Association but are, nevertheless, in current psychiatric use on the North American continent, such as pseudoneurotic, process, and reactive schizophrenia.

Another modification encountered in psychiatric textbooks and quite frequently in psychiatric practice is a nosological hybrid with German name *Pfropfschizophrenie*. Translated literally, it means "grafted schizophrenia," and it refers simply to schizophrenia occurring in a mentally retarded patient. The combination of primary intellectual defect and the effects of a psychotic process (schizophrenia) may result in manifestations that sometimes present diagnostic difficulties. They are more likely to occur in young individuals, where one is not certain whether the observed

mental deterioration is entirely the result of an early and fulminant schizophrenic process or is partly due to a preexisting mental deficiency. A careful history of the patient's early development and school achievements—establishing or eliminating primary mental retardation—is usually the best instrument for differential diagnosis in these conditions.

Those atypical psychoses that are particularly difficult to reconcile with the accepted diagnostic classifications have become the subject matter of special nosological research. In recent years a new classification for the atypical psychoses has been proposed by the German psychiatrist Leonhard, who has devoted much of his life to the study of these conditions. His ideas have also been discussed by psychiatrists outside Germany and have met with an interested response in Britain.

Leonhard distinguished atypical cycloid psychoses and atypical schizophrenias. He considers these classes of atypical psychoses as independent nosological entities that have their own genetic characteristics and are not merely idiopathic variations or mixtures of the two groups of typical psychoses, manic-depressive and schizophrenic.

Leonhard justified the separation of his atypical psychoses from the nuclear group by noting the much greater range of variation in the symptomatology of the atypical psychoses. He found further confirmation of his independent groups in the fact that his atypical psychoses have a different transmission—that is, a much higher rate of genetic transmission—than the typical schizophrenias. In his material of 826 typical schizophrenias, the incidence of mental disease in the siblings was 5.3 per cent. Among 203 atypical schizophrenias, the corresponding percentage was 13.3. Similarly, he could demonstrate a higher incidence of suicides in the family histories of atypical schizophrenias when compared with typical—or, as he refers to them, systematic—schizophrenias. The prognosis is, in general, much poorer for the atypical schizophrenias than for the cycloid psychoses, and among the atypical schizophrenics the prognosis is most guarded for the schizophasic patients, who often remain chronically ill or may recover with a permanent personality defect.

Atypical cycloid psychoses. The cycloid psychoses, which are characterized by phasic recurrences, Leonhard subdivided into three forms: motility psychoses, confusional psychoses, and anxiety-blissfulness psychoses. In the third form of these cycloid psychoses a bipolarity is expressed in its hyphenated name. The first one is clinically divided into hyperkinetic and akinetic motility psychoses, and the second into excited and inhibited confusional psychoses.

Leonhard stated that, within the group of atypical cycloid psychoses, periodic recurrences are most frequent in the motility psychoses; they are less frequent in the anxiety-blissfulness psychoses and are still

rarer in the confusional psychoses. Complete recovery of the patient is the rule in all these conditions.

Motility psychoses. In the hyperkinetic form, the motility psychosis—a term originally proposed by Wernicke—may resemble a manic or catatonic excitement. A hyperkinetic motility psychosis may be distinguished from the manic state by the presence of many abrupt gestures and expressive movements that seem to be the result of autonomous mechanisms and are apparently not responses to environmental stimuli or expressions of the patient's mood. A hyperkinetic motility psychosis may be distinguished from catatonic excitement by the absence of stereotyped and bizarre movements.

The akinetic form of Leonhard's motility psychosis, as judged from his descriptions, seems to be identical with the typical picture of a catatonic stupor. He separated these states from typical schizophrenia mainly on the basis of their rapid and favorable course, which does not lead to any personality deterioration.

Confusional psychoses. The excited confusional psychosis must be distinguished from some confused manic states. The difference can be found mainly in the greater lability of the patient's emotional state, which may be characterized by prevailing anxiety rather than euphoria. These patients are not so distractible as the manic, they often misidentify persons in their environment, and the incoherence of their speech seems to be independent of a flight of ideas.

The inhibited confusional psychosis shares with the catatonic stupor and the akinetic motility psychosis the symptoms of mutism and greatly decreased motor behavior. It differs from these states by the preservation of better self-care and greater spontaneity and by the absence of negativism.

Anxiety-blissfulness psychoses. The anxiety phase of the anxiety-blissfulness psychosis may very much resemble the picture of what is generally known as agitated depression, but it may also be characterized by so much anxious inhibition that the patient can hardly move. Periodic states of overwhelming anxiety and paranoid ideas of reference are characteristic of this condition, but self-accusations, hypochondriacal preoccupations, and other depressive symptoms as well as hallucinations may accompany it.

The blissfulness phase manifests itself most frequently in expansive behavior and grandiose ideas, which are concerned less with self-aggrandizement than with the mission of making others happy and of saving the world. In women, the dominant emotion is usually one of passive ecstasy, often the result of phantastic religious delusions that to most of us would appear to be almost pathognomonic of schizophrenia.

Atypical schizophrenias. Leonhard said that the atypical schizophrenias, which carry a poorer prognosis than the atypical cycloid psychoses, may be considered their malignant relatives. In his system he distinguished three different atypical schizophrenias:

affect-laden paraphrenia, periodic catatonia, and schizophasia.

Affect-laden paraphrenia. Patients suffering from affect-laden paraphrenia express manifold delusions, which may be well systematized. They receive their characteristic color through the strong and sustained affect that pervades them. This affect is pathological, although it may be an appropriate reaction to the content of the delusions, and it may be expressed as irritability, anxiety, or ecstasy. A certain likeness of symptoms may make the differentiation from an anxiety-blissfulness psychosis sometimes difficult, particularly at the beginning of the psychosis.

Periodic catatonia. This differs from typical schizophrenic catatonia by the periodicity of its excited or stuporous phases. It may sometimes resemble an akinetic or hyperkinetic motility psychosis, but it usually presents distinctive symptoms of stereotypy, bizarreness, grimacing, and a peculiar mixture of akinetic and hyperkinetic manifestations at the same time.

Schizophasia. This is characterized by a profound thought disturbance that results in a disorder of concept formation and abstract thinking and expresses itself in marked incoherence of speech. Such patients may at times resemble excited confusional psychotics and at other times resemble excited catatonics.

Suggested Cross References

The diversity of manifestations of psychiatric disorders that are seen in different ethnic settings illustrates the importance of social and cultural influences on behavior. Discussions of the social, cultural, and familial determinants of psychological functioning may be found in Chapter 4, on the sociocultural basic sciences.

32.2 POSTPARTUM DISORDERS

WILLIAM C. NORMAND, M.D.

The omission of postpartum psychosis from the official nomenclature reflects the current view that it is not a discrete nosological entity. The concept of a postpartum syndrome or reaction, however, retains a place in current psychiatric thought because the variety of conditions subsumed under the heading are linked by certain practical and theoretical considerations. Parenthood is an event of universal importance, rich in psychological ramifications; and reactions to it tend to form patterns exhibiting psychological unity.

The postpartum syndrome may be defined as any psychiatric disorder in which childbirth is one of the interacting causal agents, a necessary but not a sufficient cause. It includes behavior classifiable as schizophrenia, depression, psychoneurosis, organic (toxic) psychosis, and a transient situational disorder regarded as within normal limits—the postpartum blues.

History

The traditional view, that the postpartum reaction is an illness of women caused by parturition, prevailed for hundreds of years and is still the common opinion of the laity and indeed of many physicians. Zilboorg, in reviewing the history of the syndrome, pointed out that Hippocrates, Celsus, and Galen all observed postpartum psychoses. Hippocrates believed that bleeding from the nipple of a woman recently delivered meant that the milk was being suppressed, an ominous sign of a possible mental disorder. This concept, in various forms, lasted into the 19th century. Esquirol discussed at length the idea that milk not secreted by the breast was directed to the brain, where it affected nerve fibers, thus causing the psychosis; he thought this possible but unlikely.

In the middle 19th century Marcé in France and in 1889 James Lloyd in the United States asserted that puerperal psychosis was not a separate clinical entity but a collection of diseases. The psychoanalytic studies of Zilboorg in the late 1920's helped to undermine the belief in a primarily organic etiology.

Epidemiology

Postpartum reactions are common but psychoses are not. The incidence of postpartum psychosis is between 1 and 2 per 1,000 deliveries. A recent survey of the literature by Thomas and Gordon revealed that the distribution of diagnoses has changed over the years. In 1911, 50 per cent were labeled manic-depressive, 14 per cent schizophrenic, 32 per cent toxic, and 4 per cent psychoneurotic. In 1958, 15 per cent were called manic-depressive, 65 per cent schizophrenic, less than 1 per cent toxic, and 20 per cent psychoneurotic. In comparing postpartum hospitalized subjects to hospitalized women who did not have postpartum disorders, Fondueur and his colleagues found that there was no significant difference in the distribution of diagnoses.

The data reviewed by Thomas and Gordon indicated that 54 per cent of cases occur in primiparas, and 46 per cent in multiparas. They reported no correlation between postpartum disorders and heredity, religion, or the sex of the child and found the data inadequate to reach any conclusions about the influence of the use of anesthesia in delivery, the birth of a dead child or one with congenital anomalies, the birth of an illegitimate child, or an abortion.

Etiology

Although the prevailing opinion in American psychiatry favors a psychological etiology, in which childbirth is a precipitating event, the organic view also has some adherents. For example, Paffenbarger et al. suggested that a cause is active during pregnancy that exerts its full effect only with the loss of a hormone-producing organ, the placenta, which he feels indicates some basically physical etiology.

This question of organic versus psychological does not appear to be important. A multicausal viewpoint seems more fruitful. Stress—biological, social, and psychological—leads to ego activities that constitute the pathology, and thus the manifest disorder depends on the wide variety of forces that influence ego function. Childbirth, with its attendant tension, pain, and physiological changes, clearly constitutes a physical stress. Childbirth is also a major psychological stress, since it represents psychosocial success, the acme of feminine psychosexual achievement, and a milestone in the developmental history of the male.

A woman's psychic function may be adequate for childbearing in usual environmental circumstances but an extremely difficult labor and delivery or painfully adverse economic or social circumstances that make

the new baby a realistic burden may tip the balance toward a postpartum reaction. On the other hand, some women are psychologically so unsuited to motherhood that the most favorable physical and environmental conditions cannot save them from a postpartum psychosis. Though discussed separately, these are interlocking concepts. For example, the effect of an economic stress depends in part on how it becomes a psychic stress and how it interacts with other stresses; and a psychic stress can become a physical one, which in turn has further economic and psychic effects.

The psychodynamics of postpartum schizophrenia, depression, and psychoneurosis are not essentially different from those found in these conditions without childbirth. However, special attention must be given to the role of childbirth and parenthood in the psychic economy. Deutsch and Benedek each discussed the many factors that lead to emotional maturity in women. Lack of emotional maturity is generally a condition of postpartum reactions, but certain dynamic constellations stand out. Conflicts relating to unconscious hostility toward the baby and toward the patient's mother are central to these dynamic patterns.

Deutsch and Bosselman described a masculine-aggressive type, who has never accepted the feminine role. Some such women are overtly homosexual and never become pregnant or, if they do, get abortions. Others are compelled to try to deny the problem by having children. Some of this group find pregnancy pleasant because of an increased sense of power and prestige, which is in part the result of the unconscious equation, baby = penis. However, they may break down when delivery makes them feel painfully feminine. With the regression that occurs, old conflicts emerge involving hostility toward her own mother, and the baby is hated as a sign of her despised feminine role.

Rejection of the baby can result also from the patient's wish to be a baby herself, dependent on her own mother. Jealousy of her child relates to the patient's own childhood wish to enjoy her mother's exclusive attention and her hatred of sibling rivals. Identification with the baby leads her to fear the same angry, greedy attitude from it that she herself feels toward her mother. As a result, she rejects the child actually or symbolically. A protective motive, the desire to save the baby from her hostility, may also play a part in the turning away. The hostility leads to guilt, and the usual ego mechanisms result in the behavioral disturbances.

Another major type of dynamic pattern that may lead a woman to reject her baby involves unresolved oedipal forces. The child is the concrete symbol of her success in achieving the childhood fantasy of displacing mother, winning father's love, and having a baby by him. This leads to anxiety and the urge to be rid of the incriminating evidence. Guilt appears and results in pathological behavior.

In men too, postpartum reactions occur. Zilboorg

feels that these are related to the need to deny successful identification with the father. For men whose resolution of the oedipal conflicts has been shaky, achieving fatherhood can arouse very painful anxiety and set into motion the type of pathological process determined by the individual history and environmental circumstances. Some of the more common reactions are depression and paranoid behavior involving denial of paternity. In a recent paper Wainwright presented 10 cases in which fatherhood led to psychiatric hospitalization.

The form of the disordered behavior does not depend only on the unconscious dynamics but also on the form of the ego's response. For example, a woman may believe that her baby has not been born and may repetitiously go through the motions of labor pains and delivery. Another woman may ignore the child and be unable to do anything except weep. A third may suffer from constant preoccupation with the idea that her baby has cancer and is doomed, although she knows that this is not true. The unconscious conflict about the wish to be rid of the baby may be the same in all, but the first is a catatonic schizophrenia, the second suffers depression, and the third has an obsessional neurosis.

Clinical Description

The clinical picture is essentially that of the underlying disorder. Some features are significant, however, in the light of the postpartum pattern. A stormy pregnancy does not always presage puerperal trouble, nor does a calm and uneventful one always mean a nonpathological delivery period. It depends, of course, on the unconscious significance of the surface behavior. The labile pregnancy may reflect an inner struggle that will be happily resolved by the birth; and a calm and happy time may result from extensive use of the defense of denial, a precarious device.

The onset is typically during the puerperium. In schizophrenia it often appears to be sudden, and the patient commonly goes from the maternity ward directly to the psychiatric unit. In the depressions, the onset is frequently more insidious, and a period of increasing disability takes place before the worried relatives bring the woman to the psychiatrist.

The symptoms center around the patient's relationship to the baby and to the maternal role, both in direct and in disguised forms. Some typical delusions and obsessions involve the idea that the baby is dead or defective. The patient may deny the entire event by means of ideas of being single and virginal, or she may have ideas of persecution, influence, or perverse sexuality. Hallucinations can contain similar material and often involve voices telling the woman to kill the baby. The behavior toward the baby usually exhibits extremes of avoidance or anxious oversolicitude. Attempts at infanticide and suicide are infrequent but do occur. Depressive symptoms can be of neurotic or psychotic degree. Obsessive-compulsive neurotic behavior is common and can readily progress to psychotic states.

Prognosis and Management

All the techniques of modern psychiatry are available for treatment, and a careful evaluation is needed to select the approach most appropriate to the particular case. A few points are special to the postpartum state. On the basis of their study of a large number of cases, Brew and Seidenberg stated that there is no evidence of any benefit from hormone treatment. The indications for electroconvulsive therapy are the same as for psychosis without childbirth, but they suggest it not be started until 4 weeks after delivery, to avoid such accidents as the dislodging of an embolus from an unrecognized thrombophlebitis. Phenothiazine medication is often effective when the clinical picture suggests schizophrenia.

The acute postpartum reaction can often be successfully treated by immediate brief psychotherapy which aims at symptomatic relief. Later, if indicated and feasible, long term psychoanalytic therapy can be carried out in order to modify the patient's underlying personality disorder. The guiding principle of the immediate therapy is to support the ego by recognizing and temporarily accepting the nature of the forces causing the pathological ego activities. Where the dynamic pattern involves predominantly dependency, Bosselman suggested that the patient be helped to minimize the functions of motherhood and encouraged to accept outside help to permit recovery, after which she can gradually assume more of the care of the child. The masculine-aggressive type should be advised to pursue activities outside the home; later, modifications can be sought to reach the best possible adjustment for mother and child. A family approach is often important to the success of this type of treatment.

Prevention is desirable but difficult. Lorand points out that the best prevention would be to treat the personality disorders before pregnancy occurs. No data are available about effectiveness of preventive measures during pregnancy. One would expect that it would be beneficial for obstetricians to recognize the psychological factors that have been discussed and to initiate some therapeutic intervention if they see danger signs in the form of undue anxiety, family dissension, obvious immaturity, or threatening social or economic factors.

Published data on the outcome of postpartum disorders indicate that the prognosis is about the same as for the same conditions not involving childbirth (Fondeur et al.), although some maintain that the prognosis for postpartum schizophrenia is better than for schizophrenia without childbirth in a comparable population (Madden et al.). In the case of postpartum depression, the large majority recover within a few months. However, the risk of another psychosis in conjunction with a future pregnancy is high, figures on recurrence rate ranging from 15 to 35 per cent. Bosselman advises doctors to be cautious about recommending further pregnancies to such women, unless important precipitating circumstances were in-

volved that will not occur again or unless therapy has brought about some improvement in the personality functioning of the patient.

Normal women also experience postpartum blues, and Markham's study of the psychological tests of normal women after childbirth and of women with postpartum disorders corroborates the clinical impression that similar unconscious dynamic forces are present. The difference is in the ego, which, in emotionally mature women, makes use of the parturition experience to resolve old conflicts and to strengthen their feminine position.

32.3 NEURASTHENIA AND HYPOCHONDRIASIS

GERARD CHRZANOWSKI, M.D.

Introduction

Definition. Neurasthenia and hypochondriasis currently represent generic, descriptive terms, rather than nosological entities. Neurasthenia implies a state of

chronic fatigue and debility. The term "hypochondriasis" denotes the presence of physical symptoms which have no basis in demonstrable organic changes. Today it is generally recognized that any part of the body may be the object of hypochondriasis; however, the term is derived from the subcostal abdominal region which was formerly held to be the anatomical seat of the disorder. In modern psychiatry, both phenomena are believed to be psychogenic in origin; both give rise to maladjustments in interpersonal relationships and a general impoverishment of personality. On the one hand, in a sense, the patient's intense preoccupation with bodily symptoms precludes awareness of underlying unconscious conflicts. On the other hand, this preoccupation deflects his energies from other activities; instead, these energies are channeled into a rigid, narrow zone of somatic "over-concern." As a consequence of this displacement, a barrier is erected which restricts the patient's contact with the environment. Concomitantly, the patient's awareness of his inhibitions in living gives rise to neurotic feelings of inferiority and self-doubt which further restrict his object relationships and contact with the environment. In some patients, an increasing tendency toward isolation and withdrawal finally reaches such proportions that these symptoms, in themselves, are considered indicative of severe psychopathology.

History. Today it is generally agreed that the terms "neurasthenia" and "hypochondriasis" are awkward and confusing, and of limited value in the nosological classification of psychiatric disorders. At the same time, however, these concepts are of considerable historical importance.

Renaissance formulations concerning the etiology of mental illness did not distinguish between physical science and metaphysical speculation. The subsequent rejection of this orientation was precipitated by the emergence of a wave of humanitarian, rationalistic and mechanistic concepts of mental disorders, and the refutation of metaphysical considerations. Thus, in his *Elementa Medicina*, published in England in the 18th century, John Brown described the nervous system in terms of 18th century mechanistic concepts and postulated that "irritability" of the nervous system could cause mental illness. Following this theory, neurasthenia came into existence as a diagnostic syndrome which referred to a weakness or exhaustion of the nervous system. As such, neurasthenia was regarded as the forerunner of all the more severe nervous disorders, e.g., hysteria, epilepsy, locomotor ataxia, general paralysis, etc.

The term "neurasthenia," to denote nervous exhaustion, was subsequently introduced into American psychiatry by George Miller Beard in 1869. Beard maintained that the nerves might "run down" as a result of overexertion or overwork. Thus, according to Beard's theory, the nerve cells operated in much the same way as a battery: when their supply of stored nutriment was depleted, they lost their natural "charge." As an

outgrowth of this concept, S. Weir Mitchell developed his rest treatment which prescribed complete rest to cure "anemia of the brain."

The influence of George Miller Beard's hypothetical model is evident in Freud's early formulations concerning the etiology of neurosis. Freud believed that Beard's concept of neurasthenia was too inclusive and proposed, instead, the broader classification of "actual neuroses," which would encompass three separate syndromes, namely, neurasthenia, anxiety neurosis, and hypochondriasis. (Hypochondriasis resulted when an anxiety neurosis was superimposed on neurasthenia.) At the same time, however, like Beard, he attributed these phenomena to physicochemical forces, rather than psychological factors. Thus, in Freud's first theory of anxiety, he distinguished between the etiological factors which produced anxiety in specific clinical entities: while the psychoneuroses were psychogenic in origin, actual neuroses had a physical basis. More specifically, in the actual neuroses, abnormal sexual practices prevented the adequate somatic discharge of chemical substances, or "toxins." Concomitantly, there was an interference with the adequate discharge of the psychic component of sexual tension, which gave rise, in turn, to anxiety. In contrast, in the psychoneuroses, the abnormal sexual functioning which produced anxiety was due to psychic factors, specifically, to repression.

Subsequently, Freud recognized the psychological nature of anxiety and neurosis. As pointed out elsewhere in this volume, however, throughout his lifetime he continued to believe that psychical and physical processes were closely interrelated and that physical processes preceded psychological manifestations. Accordingly, Freud's later theory of anxiety did not rule out the possibility that there was a direct somatic relationship between sexual conflicts and anxiety in certain neurotic conditions or, more accurately, that these conditions resulted from the toxic effect of dammed up sexual energy.

He also maintained that there was a potential link between actual and psychoneurosis, that the symptoms of an actual neurosis might precipitate psychoneurotic symptoms in many instances. And, in this connection, he postulated a possible relationship between neurasthenia and conversion hysteria, and between hypochondriasis and paranoia. For example, initially, the pain which accompanies a neurophysiological symptom, such as a headache, is "real"; that is, it is somatic in origin and due to sexual "toxins." This actual physiological disturbance may then become a future source of focal irritation which might serve as the basis for psychoneurotic symptom formation. Freud further postulated that hypochondriasis represents a withdrawal of interest or libido from objects in the outside world; instead, the libido formerly connected with the ideas of objects now intensifies all ideas concerning body organs. In para-

noia, too, an organ becomes the representative of an external object, as a result of narcissistic regression. Thus, Freud hypothesized that hypochondria is the somatic basis of paranoia, just as the anxiety neurosis, that is, a continual readiness to "explode," is the somatic basis of hysteria.

Freud's theoretical foundation for the relationship between the conditions mentioned above is to be found in his concept of narcissism. He distinguished between ego libido and object libido. The former is a withdrawal of interest from object relations and runs counter to the capacity of gaining genuine satisfaction. Freud stated in "On Narcissism," "the relation of hypochondria to paraphrenia is similar to that of the other actual neuroses to hysteria and the obsessional neurosis: which is as much as to say that it is dependent on the ego-libido . . . and that hypochondriacal anxiety, emanating from the ego-libido, is the counterpart to neurotic anxiety."

Finally, a historical review of neurasthenia and hypochondriasis must include the formulations of Pierre Janet. Janet subdivided neurotic disorders into two groups—hysterical and psychasthenic. Within this framework, neurasthenia was described as a prolonged state of fatigue, without somatic basis. Instead, Janet postulated that neurasthenia was due to a psychic depression in which there is a general depletion of mental energy.

Current Diagnostic Classification

By definition, clinical diagnosis facilitates the prediction of course, duration, and outcome of a particular disorder. Diagnosis is also a prerequisite for the determination of the incidence and prevalence of psychopathology, and it constitutes an essential tool in determining preventive measures. Neither neurasthenia nor hypochondriasis can fulfill these criteria. For one, in many respects, they are overlapping phenomena. Secondly, they rarely appear as isolated neuroses. Rather, they usually represent complicating factors in some other psychopathological condition; in fact, neurasthenic and hypochondriacal manifestations are almost ubiquitous in all types of psychiatric practice. Finally, to further confuse the nosological picture, neither of these clinical syndromes has been described definitively.

It is not surprising, then, that the nosological classifications of neurasthenia and hypochondriasis are not included in the standard nomenclature of the American Psychiatric Association. However, the diagnostic category, "psychophysiologic nervous system reaction" includes psychophysiological asthenic reactions in which general fatigue is the predominant complaint, although there may also be associated visceral complaints. This term includes many of the conditions which were formerly described as "neurasthenia." According to the *Diagnostic and Statistical Manual* of the American Psychiatric Association, "In some instances, an asthenic reaction may

represent a conversion reaction; if so, it will be so classified, with asthenia as a manifestation. In other instances, it may be a manifestation of anxiety reaction, and should be recorded as such." Finally, the British *Classification of Mental Disorders* still lists neurasthenia under "exhaustion states," which is a subgroup under the major category, "neurosis and psychoneurosis."

Epidemiology. The difficulties inherent in an attempt to investigate the epidemiology of clinical entities as poorly defined as hypochondriasis and neurasthenia are self-evident. A major obstacle arises from the fact, mentioned above, that these conditions typically occur in association with other neurotic, psychotic, and organic syndromes. Indeed, few studies have been undertaken in this area. However, some of the findings which emerged from the study by Hollingshead and Redlich of the relationship between social class and mental illness are relevant in this connection. Specifically, these authors reported that heightened concern with bodily symptoms was most pronounced in those patients who were socially and economically deprived. Again, Anna Freud found that hypochondriasis occurred only rarely in children, unless they were motherless and had been institutionalized. On the other hand, precursors of neurasthenia and hypochondriasis, in the form of "growing pains," fatigue, and sleep disturbances, are fairly common in children.

Etiology

A brief summary of the historical evolution of current etiological concepts may be useful at this point. As mentioned earlier, Beard postulated that fatigue and overwork might give rise to mental disorders. Freud agreed with Beard in principle; this is, he too believed that mental phenomena had a physiological basis. However, Freud was less convinced of the etiological importance of overwork. Rather, Freud believed that neurasthenia could be explained as a disturbance in sexual functioning, specifically, the inadequate discharge of sexual energy. Thus, he wrote that neurasthenia "arises whenever a less adequate relief takes the place of the adequate one, thus, when masturbation or spontaneous emission replaces normal intercourse." Freud thought that every neurosis has a sexual etiology. However, he postulated a major difference between the actual neuroses and the psychoneuroses. The former group of disorders has its origin in the here and now, while the psychoneurotic conditions relate back to traumatic experiences in infancy. Finally, Freud also contended that the actual neuroses (i.e., neurasthenia, hypochondriasis, and anxiety neurosis) frequently functioned as a focus for neurotic symptom formation.

Bleuler, too, rejected Beard's hypothesis that exhaustion of the nervous system caused neurasthenia. On the contrary, he believed that work was beneficial, and he noted that individuals who work hard seldom

fall victim to neurasthenia. Bleuler also noted that neurasthenia was frequently a precursor of schizophrenia.

Current etiological concepts. Brenner summed up the situation in his *Elementary Textbook of Psychoanalysis* as follows: "...the category of the actual neuroses has ceased to be a significant part of psychoanalytic nosology." The same author, in collaboration with Arlow, expressed renewed interest in hypochondriasis, which is the third of the actual neuroses. According to Brenner and Arlow: "...hypochondriacal impulses are not properly explainable as the result of libidinal regression and displacement... they are more satisfactorily explained in terms of the conceptual framework of the structural theory, with its emphasis on anxiety, conflict and defense." Otherwise, current psychoanalytic literature has largely ignored the actual neuroses, in spite of the great interest in ego psychology with its emphasis on reality factors. For the most part, references to neurasthenia and hypochondriasis in the current literature do not extend beyond the description of these conditions. Concomitantly, when they are included, discussions of etiology are usually limited to a brief allusion to heredity, constitution, autointoxication, and prolonged emotional disturbances as major etiological factors. There has also been a growing dissatisfaction with outmoded terminology in recent years. Noyes, for one, has taken issue with the concept that neurasthenia represents an exhaustion of the nervous system. Rather, he believes that, invariably, neurasthenia is due to personal maladjustment. On another level, Masserman has described neurasthenia as an exhaustive-regressive state, due to unconscious, cumulative, internal tensions.

Harry Stack Sullivan's concern with the etiology of neurasthenia and hypochondriasis reflected his interest in the reformulation of psychiatric syndromes in interpersonal terms. To begin with, he contended that the diagnosis should pertain to an ongoing process which would be considered indicative of the way in which personal situations have become integrated in more or less durable patterns. The integration has its roots in significant interpersonal constellations of the past as well as of the present. Furthermore, personal encounters in the immediate future are an integral part of the situation, for past and present events tend to determine future experiences. Viewed from this perspective, Sullivan could find no virtue in the diagnosis of neurasthenia, as a one-dimensional, somatic concept which made no reference to maladjustments in patterns of living. He postulated, instead, that certain factors, such as deficiency states, malnutrition, and chronic intoxication, might produce neurasthenic symptoms which were purely physiological in origin. On the other hand, psychiatric or interpersonal phenomena might produce symptoms, such as fatigue, apathy, and somnolent detachment, which resembled neurasthenia to some degree. Apathy and somnolent

detachment were conceived of as protective operations against a lowering of self-esteem. More specifically, by taking refuge in sudden, overwhelming sleepiness, the individual withdraws from a tension-producing situation and is no longer vulnerable to feelings of inadequacy, worthlessness, or hostility. In apathy, all the individual's responses become less intense as a reaction to severe frustration.

Sullivan viewed hypochondriasis as a particular kind of security operation. The self-esteem of the hypochondriac has been organized in such a fashion that bodily phenomena are given a great deal of highly pessimistic attention. For the hypochondriac, an intense, morbid preoccupation with his body serves as a distraction from a stressful interpersonal situation. And, concurrently, the recognition of anxiety is minimized or avoided. The hypochondriacal person has difficulty in achieving any genuine satisfaction, because he is constantly haunted by the shadow of impending doom. Hypochondriasis is further characterized by an implicit symbolism which is body-centered and reflects a regression of cognition. It is this regression of the cognitive operations which links the hypochondriacal thought processes to certain schizophrenic thought processes. Sullivan formulated his ideas on the subject as follows: "It is as if the hypochondriacal patient had abandoned the field of interpersonal relations as a source of security, excepting in one particular. He has to communicate data as to his symptoms; the illness, so to speak, becomes the presenting aspect of his personality."

It was also Sullivan's opinion that, in all likelihood, paranoid, algolagnic, hypochondriacal, depressive, and obsessional states were different manifestations of the same maladjustive processes. He observed that in many patients there was a blending of these conditions and an alternation between one state and another.

Another etiological basis for neurasthenic and hypochondriacal preoccupations may be the existence of unexpressed anger which leads to concealed resentment. This concept has been stressed in particular by Rado, who believes that hypochondriasis serves to obscure the feelings of repressed rage and hurt pride.

Finally, symbolic feelings of rejection and worthlessness may be communicated in characteristic patterns of nonverbal and verbal communication. For example, Weinstein pointed out that the statement "I am tired" results from a complex interpersonal transaction which expresses a particular relationship to the environment. Similarly, a hypochondriacal preoccupation may be understood as a symbolic expression of feeling disliked, not approved of, and isolated from other people.

Clinical Description

Neurasthenia is characterized by a wide variety of symptoms. Usually, there are prolonged feelings of weakness and fatigue, many aches and pains, as well

as strange physical sensations. Insomnia and irritability occur often, together with feelings of chronic distress which are associated with a specific organ system of the body.

In his clinical description of neurasthenic manifestations, Freud also stressed the occurrence of headache, spinal irritation, and dyspepsia, with flatulence and constipation. Adolf Meyer felt that the term "neurasthenia" should be used only in the presence of great exhaustion and irritability. He considered the determining factor in arriving at the diagnosis to be the patient's mental attitude regarding the speed with which he recovered from feeling tired. Other symptoms which he ascribed to neurasthenia were feelings of pressure in the head, palpitations, gastric disorders, the presence of phosphate and oxalic acid in the urine, and sexual disturbances.

Some hypochondriacal patients experience vague general discomfort; however, others center their attention upon a particular organ. While any part of the body may be affected, gastrointestinal symptomatology is especially frequent. Adolf Meyer observed that hypochondriasis usually occurred in combination with other forms of nervousness. It was his opinion that the preoccupation with feelings of ill health encouraged excessive self-concern. Thus, the hypochondriac centered all his attention and interest on the potential malfunctioning of his body. Such a person might become deeply concerned over trifles and seek reassurance from quack literature. The patient's fears tend to assume a central position in his thought processes.

Management

At one time or another, almost the entire armamentarium of psychotherapeutic tools has been utilized in the treatment of neurasthenic and hypochondriacal manifestations. The results achieved with psychological reassurance, the administration of placebos, and hypnosis have been generally unsatisfactory. The effectiveness of psychoactive drugs has also been limited. In some cases, psychotherapy has uncovered an underlying depression or a latent schizophrenic process. For reasons noted earlier in this section, the hypochondriacal preoccupation may assume the character of a fixed paranoid delusion, which usually has a poor prognosis. When there is evidence of suicidal tendencies and the patient's abnormal preoccupation with somatic symptoms persists to the degree that the possibility that he may break off all communication appears increasingly imminent, hospitalization should be considered.

As a general rule, careful psychiatric evaluation is a prerequisite for the patient with a long history of the neurasthenic or hypochondriacal symptoms. On the basis of this initial assessment, the psychiatrist can determine whether the patient's symptoms are, in fact, amenable to therapy and, if so, what type of treatment is likely to produce the best results. It is understood, of course, that patients are not always

sufficiently motivated to change, although their symptoms are very distressing. In some patients, group therapy, family therapy, or even brief psychotherapy may help considerably. But other patients, who are not particularly verbal, may require quite a different approach, e.g., physical exercises, body reorientation programs, and various educational programs. In some instances, where an unhappy marriage, a difficult job situation, or family conflicts play a major role in symptomatology, a drastic change in the patient's external circumstances may produce significant improvement. Unfortunately, however, patients are not always in a position to modify their life situations.

Whatever treatment procedure is employed in dealing with neurasthenic and hypochondriacal conditions, the therapist's most difficult task will be to widen the patient's limited field of communication, so that his interpersonal relationships may acquire new depth and meaning. When therapy is successful, patients frequently become alert to areas of vulnerability and hypersensitivity in their relationships with others and in their own intrapsychic functioning.

In summary, neurasthenia and hypochondriasis are the legacy of a psychiatry whose approach to mental disorders often neglected what might be described as the "human frame of reference." In fact, both these conditions can best be understood as distorted modes of relating to the environment, i.e., where there is marked disturbance or an absence of meaningful interpersonal communication. Thus, hypochondriasis and neurasthenia may be regarded as symbolic expressions of self-experiences of worthlessness and rejection. The individual reacts to these experiences by attempting to attenuate all interpersonal contact by intense preoccupation with his own body. As a result of his focal interest, the individual becomes increasingly isolated from other people, and, in time, his somatic preoccupation also fosters a remodeling of all significant patterns of communication with the environment.

slight lowering of mood are also present. It should be noted that this diagnosis is *not* included in the *Diagnostic and Statistical Manual* of the American Psychiatric Association.

Epidemiology

This type of depression seems to be universal. Watts reported that it represents approximately 24 per cent of all new psychiatric cases seen by the general practitioner of medicine. There is a paucity of this type of depression in public mental hospitals, since the majority of cases are not of sufficient severity to require hospitalization. Similarly, it is difficult to estimate the percentage of cases treated in general hospitals. The incidence is much higher in females than in males—two to four times higher in the younger age groups but tending to be of more equal sexual distribution in the older age group.

Etiology

The cause of this kind of depression has not yet been clarified and is no closer to being discovered than are the causes of other types of depressive reactions.

Psychobiological theory. A reasonable psychobiological theory is that the depression originates as a result of some disorder of the diencephalic centers that control mood, sleep, weight, metabolism, and level of consciousness. From animal studies, it has been demonstrated that disturbance in the diencephalic and surrounding areas can produce the biological concomitants seen in depression. Some authorities postulate a combination of biochemical and environmental factors as precipitating the dysfunction.

Psychodynamic theories. The theories developed by Abraham, Freud, Fromm, Rado, Bibring, and others indicate that the premorbid personality, the precipitating factor, and the evolution of the depression are paramount in the development of depression. The premorbid personality is developed early in life, when the infant is confronted with certain frustrations that create conflict, resulting in ambivalence. Later in life, other persons become symbolic of this original conflict. The precipitating factor of depression is the loss of a loved one or threat of loss by illness or rejection. There is also identification of self with the lost love object, which is handled by introjection. Depression then occurs as a form of punishment to both self and the symbolically internalized lost love object. It should be noted however, that the syndrome of nonpsychotic cyclic depression described here does not occur in reaction to a loss or to rejection.

Clinical Description

The onset of this type of depressive illness varies from an acute attack of several weeks' duration to a slow, insidious onset extending over several years. A change in disposition generally precedes other symptoms, and this change is not noticed by the patient.

32.4 NONPSYCHOTIC CYCLICAL DEPRESSION

HAMILTON FORD, M.D.

Nonpsychotic cyclic depression is a particular psychiatric complex to which a number of descriptive terms—endogenous, simple, autogenous, Kraepelinian-type, atypical, periodical, and mild depression—have been variously applied. As these terms indicate, this form of depressive reaction is not of psychotic proportions; it is neither reactive nor hereditary in nature, and it shows very little psychomotor retardation. This condition represents a *specific episode of depression* taking place at some point or points in the life cycle, and it develops in a personality structure characterized by stability and socioeconomic accomplishments. Much of the depressive anxiety may be somatized, although such characteristics as loss of biological drive, loss of interest, a variable insomnia, indecisiveness, fear of not awakening, strong feelings of inner unrest, and a

Usually there also develop other prodromal symptoms of slight mood disturbance, periods of inefficiency at work, some difficulty with sleeping, loss of appetite, and physical symptoms without organic cause.

As the illness progresses, it becomes characterized by loss of drive and confidence, increasing feelings of guilt, indecisiveness, worry over trivialities, feelings of inadequacy, aversion to responsibilities, rumination about insignificant matters, generalized loss of interest, decreased ability to concentrate, loss of sexual drive, and an increasingly depressed mood. The characteristic sleep disturbance is classically terminal, although there may be an associated initial disturbance. The symptoms usually follow a diurnal variation in that they are worse in the morning, but, as the depression progresses, they tend to remain constant.

In the overt illness, physical symptoms are common and result from somatization of depressive anxiety. These symptoms may involve any or all body systems, but those pertaining to the gastrointestinal tract are by far the most prevalent.

Differential Diagnosis

The differential diagnosis of nonpsychotic cyclic depression includes anxiety reaction, depressive reaction, involutional psychotic reaction, manic-depressive reaction (depressed type), psychotic depressive reaction, schizophrenic reaction (schizoaffective type), and early cases of chronic brain disorders. Differential diagnosis is not difficult to establish with a careful longitudinal history, mental status examination, psychological testing when indicated, adequate physical examination, and appropriate laboratory studies.

Prognosis

The prognosis of nonpsychotic cyclic depression is excellent with adequate treatment. There is always the possibility of recurrence, but, if the previous depression or depressions have responded rapidly to treatment, the outlook for recovery in each episode is good.

Early diagnosis and treatment, with currently available modalities, usually reduce the length of the illness. Marked somatization or obsessive traits seem to prolong the illness.

Management

Treatment consists of supportive and symptomatic therapy or specific therapy, depending on the degree of depression. Mild depression usually responds to supportive and symptomatic therapy; more severe depression may require specific treatment. It is most important to establish a positive diagnosis early in the course of the illness so that somatic symptoms are not reinforced.

Supportive and symptomatic treatment. This type of therapy should consist of attention to diet, sleep, reduction of responsibility, and curtailment of social engagements. Antidepressant medications, when indi-

cated, should be tailored to suit the symptoms. Reassurance and supportive psychotherapy tend to dispel fears and uncertainties and may also give some relief from other symptoms. Mild depressions thus treated show about 70 per cent good improvement, requiring no further treatment. Those cases that do not respond in a reasonable length of time should receive specific treatment.

Specific treatment. This consists of electroshock therapy with or without antidepressant medication. Hospitalization is indicated, at least initially, for electroshock treatment. Approximately 90 to 95 per cent of cases recover within a 2-month period on this treatment program. In treatment failures, a maintenance electroshock program for as long as 6 to 12 months may be required to obtain a full remission of the illness. The effect of electroshock treatment on one episode has no bearing on the development of further episodes of depression. There is some indication that the combination of appropriate chemotherapy and electroshock treatment may reduce the total number of shock treatments needed to interrupt the illness. Recent studies with continuous low voltage, direct current stimulation to the frontal areas of the brain show promise as a definitive therapy.

There is evidence that psychotherapy of an uncovering nature is not indicated because it can aggravate guilt feelings, enhance tension, and deepen the depression. Self-injury is not common in this type of depression, but revelatory psychotherapy carries the risk of suicide because of the psychodynamics involved.

THE PSYCHIATRIC SYNDROMES

Chapter 33

Psychiatric Emergencies

33.1 SUICIDE

HERBERT HENDIN, M.D.

Suicide has occurred since the beginning of recorded history, with attitudes toward it varying from the condemnation of the early Hebrews to the tolerance of the ancient Greeks and Romans. Both the motives for suicide and its frequency have also varied from culture to culture. Even among primitive cultures, there are those with much higher suicide rates than our own and others where suicide is virtually unknown.

Epidemiology

In the United States, suicide is the 10th major cause of death, with 20,000 suicides recorded each year. It is estimated that each year there are about 10 times that number of attempted suicides. These figures do not fully reflect the magnitude of the problem. Some suicides are concealed. Other probable suicides are not recorded as such because of insufficient proof that a suicide rather than an accident was the cause of death. Since suicide (*sui* = self, *cide* = murder) is defined as the intentional taking of one's own life, the figures do not reflect unconsciously motivated fatal accidents or the many varieties of self-destructive behavior that are psychologically related to suicide.

The average yearly United States suicide rate of 10.5 per 100,000 places this country in the middle of any international scale. Ireland, Chile, and New Zealand, for example, consistently have suicide rates below 6 per 100,000; Japan, Denmark, Sweden, Austria, West Germany, and Hungary have suicide rates averaging 20 per 100,000.

The suicide rate for men in the United States averages 16 to 17 per 100,000 with the female rate about 4 to 5 per 100,000. A ratio of between 2 and 4 to 1 of male to female suicides is present throughout the industrialized world. This is in contrast to the ratio of attempted suicides, which are twice as frequent among women.

The tendency for suicide to increase in frequency

with advancing years is present in all Western countries. For children under 15, the suicide rate is negligible; for men over 65, the United States rate is over 50 per 100,000. The male suicide rate in this country rises steadily with age till 85; the rate for women reaches a peak between 55 and 65 and declines thereafter.

Suicide has a lower frequency among the married, especially those with children, than among the single, widowed, or divorced. Suicide rates for the single population in corresponding age groups average twice those of the married; suicide rates for the widowed and divorced are four to five times higher than those for the married population.

In the United States, the highest suicide rates are seen at the bottom of the socioeconomic scale. Unskilled laborers and agricultural workers have suicide rates significantly higher than the national average; professional groups and highly skilled workers have suicide rates below this average. This is a somewhat different picture from that found in Europe, where the top as well as the bottom of the socioeconomic ladder has the highest suicide rates, with professional groups, such as physicians, often ranking quite high.

The United States also differs from Europe in the ratio of urban to rural rates. In Europe, urban areas have strikingly higher suicide rates than rural areas. This pattern also prevailed in the United States until 30 years ago, but differences between urban and rural areas have now become negligible in this country.

Predominantly Catholic countries—such as Italy, Spain, and Ireland—have lower suicide rates than countries with a predominantly Protestant population. There are, however, some important exceptions. Norway and the Netherlands are Protestant countries with very low suicide rates, and Catholic Austria has one of the world's highest suicide rates. Within the individual European countries, higher suicide rates are present among Protestants than among Catholics. The Jewish rate in Europe has fluctuated greatly throughout this century, although it is generally lower than that for Protestants. In the United States, Protestants show significantly higher suicide rates than Jews and Catholics.

Within the United States, cultural and subcultural influences on the problem of suicide are easily discernible. Suicide rates among the foreignborn in the United States are higher than those of the nativeborn. The rates tend to be comparable with those of the country of origin, so that high rates are seen for those of German or Swedish origin and low rates for those born in Italy or Ireland. The Negro suicide rate in the United States is low, averaging one third that for whites. In urban centers, however, the Negro rate is much closer to that of the white population.

In this country, over one half of the male suicides and one fourth of the female suicides are carried out through the use of firearms. Poisoning by gas, solids, and liquids accounts for most of the female suicides—over one third of the total figure. Among men, poisoning contributes less than one fifth of the total. Hanging and strangulation account for one fifth of both male and female suicide.

The methods employed by suicides vary from place to place depending on availability. Jumping from high buildings is insignificant for the United States as a whole, but accounts for 15 per cent of the suicides in New York City. In Denmark, where private possession of firearms is illegal, suicide by firearms is virtually nonexistent, but the percentage of hanging rises to contribute 35 per cent of the total Danish figure.

Transient suicidal ideation may be seen in most people, but in our culture, actual suicide attempts usually reflect some underlying emotional disturbance. Attempts to correlate suicide with a variety of clinical syndromes ranging from alcoholism to homosexuality are often misleading, since an emotionally disturbed group is likely to have a higher incidence of other signs of emotional disturbance than the population as a whole. Although occasional families with histories of multiple suicides are encountered, Kallmann's genetic studies of suicide in twins have ruled out the possibility of a special genetic factor predisposing a person to commit suicide.

Sociological and Psychological Approaches

Durkheim. The first major contribution to the study of the problem of suicide was made at the end of the last century by the French sociologist Emile Durkheim. Many of his basic concepts are still actively in use, although sociologists have refined and extended his original contribution.

Durkheim utilized the European suicide figures to focus attention on some of the characteristic statistical patterns noted above. Suicide was more common in cities than in rural districts; there was more suicide among the single and the divorced than among the married and more among the married who were childless than in parents; it was seen more frequently in men than in women, more frequently among the wealthy than the poor, and more frequently among Protestants than Catholics.

In an attempt to explain these statistical facts,

Durkheim divided suicides into three social categories—egoistic, altruistic, and anomic. Egoistic suicide comprised individuals who were assumed not to have been strongly integrated into any social group, regardless of whether that group was a family, a religion, or a community. Family integration or the lack of it could be used to explain why the unmarried were more vulnerable to suicide than the married and why couples with children were the best protected group of all. Rural communities had more social integration than urban areas and thus less suicide. Protestantism was a less cohesive religion than Catholicism, and Protestants thus had a higher suicide rate than Catholics.

Altruistic suicide described the group whose proneness to suicide stemmed from exactly the opposite factor, that is, their excessive integration into a group, with suicide being the outgrowth of this integration. Durkheim had in mind the kind of suicide that in special situations could be expected of certain classes in Japanese society and the kind of integration into a military group that could at times require an individual to sacrifice his life.

Anomic suicide occurs when there is a disturbance in the balance of the individual's integration with society that leaves him without his customary norms of behavior. Anomie could explain the greater incidence of suicide among the divorced as compared with the married and the greater vulnerability of those who had undergone drastic changes in their economic situation. As a corollary of anomie, greater vulnerability to suicide was seen to exist among those in the society who had wealth or status and thus had more that they could potentially lose. It is among the wealthy who have had money and lost it, and not among the poorer classes, that one sees an increase in suicide during periods of economic depression. Sociologists could explain the low Negro suicide rate in the United States as due to the Negro's lower status and consequently lesser vulnerability to anomic suicide.

Increases in anomic and egoistic suicide were felt by Durkheim to be responsible for the rising suicide rates of Europe. The rise originated in a "pathological state just now accompanying the march of civilization without being its necessary condition." With industrial and scientific development, neither the family, the state, nor the church were the forces for social integration they had once been, and nothing had been found to replace them.

In essence, Durkheim's contribution was the introduction of the social dimension into the problem of suicide. He showed that suicide—like crime, neurosis, and alcoholism—is a factor that measures social pressure and tension. The extremely high rate seen in West Berlin in the postwar period is perhaps the most dramatic manifestation of this principle.

Durkheim's social categories were used to explain the variations in the rate of suicide from country to country. The Catholic countries had low suicide rates in line with Durkheim's observations on the influence

of Catholicism. Low rates were seen in impoverished countries like Spain and Ireland, although here a combination of being both poor and Catholic may have been at work. Such wide application of Durkheim's work was bound to highlight some of its weaknesses. No satisfactory explanation was given by Durkheim or his followers for Austria, a Catholic country with one of the world's highest suicide rates. No adequate explanation for the Scandinavian phenomenon of the strikingly high Danish and Swedish suicide rates as compared with the low rate in Norway could be found in Durkheim's categories.

Durkheim was neither oriented toward nor interested in the psychology of the individual suicide. This attitude was but an extension of his general feeling that "social facts must be studied as things, as realities external to the individual" and that, therefore, the psychology of the individual had little relevance for sociology. Since we are still busy resolving the problem of effectively integrating psychological and sociological data, it would not be fair to criticize Durkheim too severely for not tackling this problem. In the light of current knowledge, it is easy to see how the omission of the individual dimension limited the contribution that Durkheim could make in his own field of interest. The ways in which different social and cultural institutions are integrated by the individual and in which they affect his development, personality, and character are important to psychology, and, since the individual is the ultimate measure of the impact of social pressures, ignoring him makes the sociologist's study of social pressures a matter of guesswork.

Freud. The first important psychological insight into suicide came from Freud. Freud did not deal directly with the problem of suicide and described only one patient who actually made a suicide attempt. What he did see, however, and in good number, were depressed patients. In his 1917 paper "Mourning and Melancholia," Freud stated that the self-hatred seen in depression originated in anger toward a love object, anger that the individual turned back on himself. He regarded suicide as the ultimate form of this phenomenon and doubted that there would be a suicide without the earlier repressed desire to kill someone else. This concept of suicide as a kind of inverted murder was extremely important, although, unfortunately, it became overworked by some in an effort to explain all suicides.

Freud's observations on depression were made long before he came to the conclusion that anger or aggression could be nonerotic in origin. At the time of the writing of "Mourning and Melancholia," Freud believed that all aggression had to have a sexual origin. Hence his paper is filled with a complex discussion of what amounts to retroflected anger. Ten years later, Freud expressed surprise at his having overlooked "the universality of nonerotic aggression." Since he never rewrote his earlier report, the extraneous libidinal explanations for the existence of anger remained unaltered. However, this fact should not lead one to overlook the basic psychological truth contained in

his paper—namely, that anger can become self-directed, can lead to depression, and can be a motivating force in suicide.

Freud's preference for instinctual explanations led him to see aggression as the manifestation of a death instinct. The death instinct violated too many basic observations of biologists and psychologists for it ever to be accepted by them or by more than a small minority of psychoanalysts. Instinct psychology soon lost much of its influence in the field of psychology, although it has held on longer in psychoanalysis. By 1922, John Dewey had already given his analysis of the misconceptions that arose from taking a phenomenon and elevating it to a cause by attributing it to an instinct. Zilboorg probably spoke for a majority of psychoanalysts when he wrote in 1937 that "to say the death instinct gains the upper hand over the life instinct is merely an elaborate way of saying that man does die or kill himself."

While Durkheim minimized the individual dimension, Freud showed a similar disregard for the social dimension. Instincts know no societal boundaries, and Freud's instinctual frame of reference did not lead him to a concern with the psychological impact of the social institutions of particular cultures nor with such psychosocial questions as why suicide was very high in one country and very low in another. Nor would his instinctual frame of reference have enabled him to resolve such questions adequately, even if they had arisen. The marked variation in the suicide rates from country to country had helped Durkheim realize that social facts were a function of social institutions, which in turn were a function of a particular society or culture. Biologically speaking, the differences between Englishmen and Germans or Norwegians and Swedes are not very important, and Freud assumed he was dealing with psychological evolution, much as Darwin had dealt with biological evolution. Being understandably under the influence of the evolutionary anthropology of his day, Freud saw the psychological life of primitive man as "a well preserved early stage of our own development." This approach made study of the culture as a unit unnecessary, and Freud had little interest in the comparative anthropology that developed during his lifetime.

More important was his influence. As late as 1936, Zilboorg was certain that investigation would show primitive man to have a much higher suicide rate than modern man. Investigation showed, rather, that primitive cultures also had marked variations in suicide rates and that there were cultures where it was unknown. In any case, separate study of each culture, its people, and its psychosocial institutions is required for any deeper understanding of the frequency with which suicide is used in a society as an expression of personal dissatisfaction and unhappiness.

Psychodynamics

A study of the psychodynamics of suicide is a prerequisite for any understanding of suicide as a psycho-

social phenomenon. In such a study, one is usually working with patients who have made suicide attempts and survived. The question as to whether these patients are comparable in terms of personality and motivation to those who actually died has a bearing on any evaluation of the psychodynamics of suicide.

Some years ago it proved helpful to rate or evaluate suicidal patients on a scale of one to three with regard to their suicidal intent—1: the patient with minimal intent; 2: moderate intent; 3: maximal suicidal intent. The following three cases illustrate types of patients in the maximal intent group.

A girl jumped under a subway train and survived, although two cars passed over her. Her survival was possible because on this particular subway there was sufficient room between the wheels and under the train. However, these details were not known by the girl at that time.

A second patient entered into a suicide pact with his homosexual partner. They made their attempt in a hotel room on a Saturday night so that they would not be discovered by the chambermaid until Monday morning. Both took 50 barbiturates of 0.1-gm. strength. When found and admitted to the hospital on Monday, they were comatose and remained so for several days. The initial opinion of the hospital staff was that neither would survive. As it turned out, one died and the other lived. The one who lived was placed in the group of maximal intent patients.

A third patient tried to shoot himself in the heart. The bullet grazed his heart, pierced his lung, and came to rest 2 cm. from his spinal cord. His survival was, according to his surgeons, little short of miraculous.

It seems reasonable to include such cases in the maximal intent group and to assume that, in working with them, one encounters a situation as close as is necessary to that resulting in actual suicide. When suicidal patients are divided into intent groups, the group with maximal intent has an age and sex distribution statistically comparable to that of actual suicide. It is quite different from the total group of all attempted suicides.

Studies of actual suicides reveal that 60 per cent of them have histories of previous attempts. However, studies in which attempted suicides who survive are followed establish that 10 per cent of them eventually kill themselves. Thus, it appears likely that the attempted suicide group is a large and heterogeneous group that in a sense contains the eventual suicide group. These studies highlight both the research value and the clinical necessity of the careful evaluation of suicidal intent.

A great deal about suicide can also be learned from the study of patients in the lower intent groups. When, for example, suicide is an act of self-punishment, for one patient only death will be sufficient atonement; for another, the self-damage done in a suicide attempt may suffice. The study of both types, however, throws light on the psychology of self-punishment and its relation to suicide. Investigation of the maximal intent group also indicates that most suicidal patients have mixed feelings about the wish to die. The attempts made in Europe by Stengel and others to regard attempted suicide as a completely separate entity from

actual suicide have been based on failure to comprehend the psychodynamics of suicide.

Since the methodological details and particular circumstances of a suicide attempt usually provide the first important clue to the psychodynamics of a particular patient, they must be carefully established. With the suicide attempt often representing a kind of psychological drama, the very way in which it is made is apt to be revealing. One woman jumped from a window with a picture of her son in her brassiere and a message on the back of the picture saying, "Timmy knows I love him." Years before, at the time of her divorce, this woman had given away her young son to his paternal grandparents, who actually raised him. Although she still saw him up to the time of the attempt, she was tortured by her difficulties in love relationships and especially by her inability to love her son. The picture and its message amounted to an attempt to deny the true state of affairs. Yet they furnished the first insight into her desire to end her life.

The communication of suicidal intent is often an integral part of the method employed. Such communication can be coercive, can be a plea for help, and, most dramatically, can involve a gamble with death in which another person is empowered to decide whether the potential suicide will live or die.

The choice of method used in a suicide attempt may reveal a good deal about the organization and integration of the personality involved. Disorganized or multiple suicidal methods or those carried out in a chaotic manner and lasting several days are usually chosen by disorganized, schizoid patients.

As has been indicated, modern concepts of the psychodynamics of suicide began with Freud's idea that suicide stemmed from anger toward a love object, anger that had become self-directed, and thus suicide was a kind of inverted homicide. It should also be recalled that Freud's theory was the outgrowth of his work with depression.

Our views of depression have been revised over the years. The significance of both dependency and expiation in depression was stressed by Sandor Rado. The idea that retroflected anger and self-punishment can have atonement or expiation as goals—with the depressed individual hoping to win back love and affection—does not appear in "Mourning and Melancholia" and was primarily Rado's contribution. Just as retroflected anger can at times be the motivating force in suicidal patients, so can suicide be an act of expiation.

Something of the relationship between suicide and depression can best be understood by the need for atonement that can underlie both. It has long been observed that depressed individuals may attempt suicide just as they appear to be recovering from their depression. It is equally true that a suicide attempt can cause a depression of long standing to disappear. One form of atonement appears to substitute for another. Of equal relevance, many suicidal patients use a preoccupation with suicide as a way of fighting off intolerable depression. So, paradoxically, at times depression seems to

ward off suicide, and at other times suicide serves to ward off depression.

Despite the help that the knowledge of the psychology of depression gives to the understanding of suicide, it is by no means the whole picture. A great number of suicidal patients do not manifest the clinical features or classic psychodynamics associated with depression. Especially important is the fact that many depressed patients are not suicidal. This observation alone serves to demonstrate that the psychodynamic aspects of depression are not sufficient to explain suicide. In other words, the study of depressed patients cannot be used as a substitute for the direct examination of suicidal patients. In such investigations, many suicidal patients appear to view their death as an internalized murder, while the suicide attempts of others are explained as acts of expiation. In addition, there is a broad range of different attitudes toward death and other meanings of the act of suicide.

Freud wrote in 1915 that the "unconscious does not believe in its own death." Some 20 years later, Zilboorg elaborated on this statement to stress the importance of unconscious fantasies of immortality, particularly for suicidal patients. It may seem surprising that not until recently has there been more systematic investigation of the attitudes and fantasies of suicidal patients toward death, dying, and afterlife. This can be attributed partly to the anxiety and inhibition of psychiatrists in relation to suicidal patients. A reflection of this attitude can be seen among the residents of psychiatric wards who ask a patient after 10 minutes' acquaintance if he has had homosexual experiences or what he does with regard to masturbation. However, they probably fail to ask a suicidal patient about his attitudes toward death, about the presumed events after death, about his thoughts after he turned on the gas, and about possible dreams during his state of unconsciousness. These four questions can elicit valuable material bearing on the understanding of suicidal patients and their motivation. The answers to them make clear that what a suicidal patient wishes to escape from in life tells us only part of his story. His attitudes toward death, dying, and afterlife must be known in order to understand fully his motivations for suicide.

The following cases illustrate some of the psychodynamic constellations with regard to death and suicide that have been observed in suicidal patients.

Death as retaliatory abandonment. An 18-year-old homosexual college boy who had been failing in school was seen after he took 60 barbiturates in a serious suicide attempt, which he barely survived. He had a simple but revealing dream in connection with his suicide attempt. He was working for the United Nations, where he had an office comprising the entire first floor of the U.N. building. He was interviewing one of his friends, who was applying for a position. After reviewing his qualifications, he told his friend that he did not qualify for the job.

During his waking associations to the dream, he revealed his preoccupation with his friend, on whom he had had a crush, although he had never mentioned his sexual interest in the boy to him. Apparently the friend became alarmed at the in-

tensity of the patient's feelings and was determined to break away from the relationship. Several months prior to the suicide attempt, he had stopped seeing the patient.

What does the patient accomplish in the dream and by his suicide attempt? He gains an illusory control over the situation in which he was rejected. In the dream, if there has to be a rejection, he is going to do it; by committing suicide, he is the one who leaves and rejects. The concept of death as an act of leaving—that is, as abandonment—is known to derive from childhood. Children's reactions to death frequently imply either that a violent act was inflicted on the dead person or that he left voluntarily. Children who lose or are separated from their mothers react as though the mothers had chosen to leave them. The continuation of this psychological equation is seen in adult patients with extreme fears of dying, which are traceable to the most primitive abandonment fears of childhood.

That the patient also experienced a *feeling of omnipotent mastery through death* is strongly suggested by the important U.N. position and large office in his dream. Suicide attempts and the possibility of suicide seem to give a person an illusory feeling of mastery over a situation through the control over life and death. Suicide can be a source of relief to patients excessively preoccupied with the fear of death through the feeling of control they then have over the when and how of dying.

Another patient, a chemistry major in college, had struggled through school with a cyanide capsule in his desk, consoling himself with the thought that, if he could not manage his work, he could always take the cyanide. On graduation, he threw it out and never made a suicide attempt. On the other hand, a female patient who eventually did make a serious suicide attempt had previously kept a toy pistol in her drawer and had comforted herself through an unhappy love affair with the fantasy that if things got too bad, she could always kill herself.

Death as retroflected murder. A 44-year-old woman made a suicide attempt with sleeping pills about a year after the breakup of her marriage. Her husband had been unfaithful during the 20 years of their marriage; she had alternately doubted these affairs or had reassured herself by saying that they were unimportant to him. However, his last affair lasted almost 2 years. Finally, she precipitated a crisis by barging in on him in the other woman's apartment. He was furious and openly moved in with this woman. About 6 months later, the patient had a rather unsatisfactory love affair with a younger man. Immediately following her suicide attempt, she stated that both her children and her husband would be better off without her. The children, a boy of 19 and a girl of 15, she said, needed a new home.

In an attempt 10 days earlier, she had gone out to a lake with the intention of drowning herself but changed her mind. She came home and took 15 sleeping pills instead, waking up by herself a day and a half later. The next time she took twice that dose. While under the influence of the first pills, she had the following dream. She saw a cap belonging to her husband's father floating on the sea and realized that he had drowned. Her husband's father had been a sea captain and closely resembled her husband, being extremely domineering, critical, and difficult to get along with. At first she saw the dream in terms of her own martyred role, but eventually she related it to her desire to strike back at her husband. She spoke vindictively of the problem the children would cause him after her death. It soon became evident that her suicide attempt

stemmed from her anger at her husband and was an indirect attempt at revenge. She was ineffective in handling both her anger and her self-assertion, and she could not even fight for her children. Her situation was like the classic one described by Freud, in which suicide represents an inverted homicide.

In many of the younger, severely disturbed, and seriously suicidal patients, suicide represents a turning in of murderous rage that is far from repressed. These individuals are potentially or actually violent, and suicide can be the outcome of a severe struggle with the overt desire to murder.

Death as a reunion. One patient made three suicide attempts over a period of 20 to 25 years. When seen for the first time, following her third suicide attempt, she was 47 years old. Each attempt had been more serious than the one before, and she was particularly fortunate to survive the last one, in which she used gas. An unhappy love affair was time-related to all three attempts. Following the third attempt, she received treatment for 2 months, during which her last love affair continued unsuccessfully. The patient then became acutely suicidal and required admission to the hospital. That night she had the following dream. "I was in Baltimore in an apartment where I lived 25 years ago. There were a lot of people around who told me to put on a beautiful wedding dress hanging on the wall, but I would not put it on."

Her associations were to the Baltimore apartment where her first romantic liaison had lasted for 2 years until one night her lover told her he was going to marry another girl. She thereupon made a suicide attempt, and everything in the dream was the same as it had been at the time of her first attempt. In the wedding ceremonies preceding her two unhappy marriages she had failed to wear a wedding dress, although she had always wanted to. She felt she had lost the really great love of her life with the end of this first relationship. What impressed her most in the dream was that the wedding dress "looked more like a shroud than like a wedding dress." Apparently, union with her first lover was to be achieved only through her death. Moreover, the patient recalled that she had had this dream recurrently before each suicide attempt. She was refusing to put on the dress while struggling, in reality, against suicide. Death was the unpleasant price she had to pay for the gratification of her desire for love and affection.

In other patients with similar but more masochistic psychodynamics, the act of dying itself can be conceived of as pleasurably incorporated into the reunion fantasy. Most frequently the emphasis is not placed on the dying but on the gratification to follow, the mood in such reunion dreams being quite pleasant. In the overwhelming majority, the gratification is of an extremely dependent variety, either directly with parental figures, or with wives, husbands, or siblings substituting as parents.

Although such fantasies are usually unconscious and have to be elicited from dreams, they can also be conscious. One patient was seen following a suicide attempt that eventually proved to be fatal. He had been preoccupied for the entire year after his wife's death with fantasies about her and with mental pictures of being reunited with her in death.

Death as rebirth. A young, intelligent woman in her twenties, well educated and successful in her work, jumped under a train and lost a leg. Her suicide attempt was precipitated by one of the unhappy and complicated love relationships with which her life had been filled. Several years earlier she had

been intensely involved with a married Negro. A few years before that affair, she had been in love with a Communist under investigation by the F.B.I.; he was at that time trying to use his relationship with her to get into the United States.

When she was 13 years old, her father deserted the family, and she never saw or heard from him again. She was fascinated by death and dying all through adolescence and could recall in detail the death scenes in novels.

The following dream concerning her suicide attempt made her wish to die more understandable. She was in a long, narrow tunnel and could see a light at the end of it. She walked toward the light, and there she saw a man and a woman standing over a manger. In her associations to the dream, the tunnel suggested to her the subway from which she jumped and the way in which the train came out of the tunnel and into the lighted platform area. Moving from the darkness of the tunnel into light brought to her mind the process of birth. The man and woman she saw as her father and mother. The child in the manger was both the Christ child and herself. One can see how much she accomplished in her death fantasy. She is reborn, is a boy, is reunited with her father, and, finally, is omnipotent. For a patient with such fantasies the thought of dying has a very strong appeal.

Death as self-punishment. A lawyer in his thirties made a moderately serious suicide attempt, which he blamed on his lack of success in a legal career. His dreams were of the most elemental kind. In one instance they revealed him running to catch a boat and just missing it. In his associations, missing the boat symbolized the low opinion he had of his entire career. His legal ambitions were excessive, and he found it impossible to compromise with his grandiose success fantasies. The aggressiveness that stemmed from this grandiosity interfered with his actual performance, a constellation frequently observed in male patients with extremely high and rigid standards for themselves. What is seen as failure causes an enormous degree of self-hatred, and suicide amounts to a self-inflicted punishment for having failed.

Many male patients in this group demonstrated evidence of a paranoid personality structure before they became depressed or suicidal. The following case is a typical example.

A 55-year-old stock broker was depressed to the extent that he had been unable to work for several years prior to his suicide attempt and subsequent psychiatric examination. Previously he had a career spanning 30 years, although he had changed positions every 2 or 3 years. Each time he claimed to have been the victim of mistreatment, personal favoritism, or corruption. Eventually, a combination of these factors and his daughter's breakdown proved too much for his paranoid defenses, resulting in the manifestation of his latent depression of long standing. He began to blame himself and his unworthiness for the failure in his work and bemoaned his misfortune with his daughter. Under psychotherapy, he became paranoid toward the therapist; significantly, at the same time, his depression lifted considerably, so that within a few months he could resume his work. With his paranoid defenses reactivated, his depressive symptomatology lessened, and he became able to function.

This type of suicidal self-punishment reaction over failure at work has not been observed in women. A suicidal self-punishment reaction that can be seen in women was illustrated by the previously mentioned patient who was unable to love her child. When a woman's inability to love her child is accompanied by the expectation that she should feel what she is not feeling, strong self-hatred with the need for self-punishment can be the result.

A variation of the view of suicide as self-punishment that occurs in patients of either sex may be illustrated in the following case.

A 30-year-old man from a relatively stable rural family as the sixth of eight children felt superfluous from early childhood. All the other siblings were married and apparently leading responsible lives, and he considered himself the black sheep of the family. From the age of 18, he was a moderately severe alcoholic. His "impossible" marriage also resulted in feelings of being superfluous and quickly ended in divorce. His main occupation had been that of a seaman, but his explosive temper and frequent fights aboard ship led to unemployment and depressed feelings. He reported the following dream, which he had immediately prior to an impulsive suicide attempt—jumping in front of a moving car. "An atom bomb was falling.... I was in hell and about to be burned. My brother was above, saying that I should be burned." The patient believed that he would end up in hell if he did not lead "a more Christian life." Eight months earlier, he had begun to attend church in order to force himself to live differently, but without success. His extremely religious mother was opposed to drinking, smoking, or any amusement for its own sake. Although he had never been close to her, he had taken over her religious beliefs, despite his inability to live up to them. The brother in the dream was the family member closest to the patient; nevertheless, their relationship had been characterized by fights and reconciliations until the time of his brother's death 3 years earlier.

During the previous 8 years, the patient had made several impulsive suicide attempts, including one where he jumped in front of a moving jeep and was severely injured. Suicide was for him an act of atonement, and death was a fair punishment for his explosiveness, his anger toward his siblings and the world, and his asocial life.

Among the most disturbed suicidal patients of both sexes seen in mental hospitals, feelings of being worthless predominate, and self-punishment is a prominent feature. The original motivation may be centered around failure, guilt over aggression, or attempted expiation; however, the self-punishment may be dissociated from these goals and thus become almost an end in itself. Such patients tend to be preoccupied with delusional feelings of guilt, sin, and unworthiness.

The patient who sees himself as already dead. One man jumped in front of a train and lost an arm and a leg almost to the hip. Some months later, he related a dream in which he was shopping for a coffin. The coffin maker told him that his coffin was only half-finished. In view of the fact that he had lost two limbs in his suicide attempt, the dream seemed to project a current picture of himself. His associations to the dream indicated that, in his opinion, only his physical death was half-completed. Emotionally, however, he felt that he had died years before making any suicide attempt.

One very withdrawn suicidal girl of 18 had a recurrent nightmare in which she saw dry ice coming closer and closer to her. It threatened to envelop her until she woke up in panic. She was tormented by her inability to feel anything for anyone. Not only did she feel dead, but her physical appearance and motility suggested a kind of walking death. The dry ice image was a self-image—a self that was seen as permanently frozen, dangerous to others, and self-destructive.

Patients of this kind are representative of an entire group preoccupied with the feeling of being already dead, generally not in a delusional sense but in the sense of being emotionally dead. Strong feelings of de-

tachment, repressed aggression, and dampened affectivity are perceived by many patients as the equivalent of emotional dying or death. Clinically, these patients may appear apathetic rather than depressed, and their suicide attempts rarely change this mood. Despite overt apathy, such deadness is experienced by suicidal patients as extremely tortuous, so that they see suicide either as a release from suffering or as merely carrying out an event that has already happened.

An attempt has been made in this section to demonstrate some of the psychodynamic patterns seen in suicidal patients in connection with different fantasies and attitudes toward death. Seven such patterns have been outlined and illustrated: death as abandonment, death as omnipotent mastery, death as rebirth, death as self-punishment or atonement, death as retroflected murder, death as a reunion, and death as a phenomenon that has, in an emotional sense, already taken place.

The death fantasy of the suicidal individual is helpful not only in revealing his motivation for suicide but also in shedding at least some light on his entire attitude toward life as well as death. The individual who expects his suicide and death to continue a punishment he deserves is quite different from the individual who hopes for the gratification of dependent desires in a protected reunion with a maternal figure. They reveal quite different character structures and not merely different suicidal psychodynamics. Death fantasies thus come to serve as a natural aid in distinguishing the various motivational psychodynamics seen in suicide.

Attitudes toward suicide, death, and afterlife also differ from culture to culture. Understanding such differences becomes an integral part of understanding suicide in its psychosocial context.

Psychosocial Approach

The necessity of a psychosocial approach to the problem of suicide is best illustrated by examination of the Scandinavian suicide phenomenon, namely, the high suicide rates in Sweden and Denmark and the strikingly low rate in Norway. Much of the attention that the high Danish and Swedish suicide rates have received is a consequence of the social welfare measures applied in the two countries. Both inside and outside Sweden and Denmark, opponents of economic planning and social welfare measures have attempted to explain the suicide rate as a consequence of character defects produced by these measures. But the Danish suicide rate has been higher than those of most other European countries for the last hundred years. The Swedish suicide rate has climbed since the turn of the century, and a better case could be made for relating this rise to Sweden's late but fast developing industrial capitalism than can be made for relating it to the relatively recent social welfare measures. Moreover, Norway has equally advanced social welfare measures and a suicide rate of 7.5 per 100,000, which

is only a little over one third that of Sweden and Denmark.

Inasmuch as Sweden has been successful in dealing with most of the economic problems that plague the rest of the world, it has been felt that her people have no right to a high suicide rate. However, it has long been known that countries with much poverty have low suicide rates. Yet one can hardly suggest planned poverty as a cure for suicide. Problems of survival can suppress psychological conflicts. This is probably one reason war has the effect of lowering suicide rates. Only as countries begin to solve the problems of survival are they in a position to become aware of the psychosocial tensions and conflicts within the culture.

Suicide is but one barometer of social tension; crime, alcoholism and neurosis are equally valid barometers, and one such index cannot be consulted without reference to all the others. For example, although the suicide rates for Sweden and Denmark are twice that of the United States, the homicide rate in the United States is 10 times that of the Scandinavian countries.

Of most interest from the standpoint of understanding suicide, however, is the fact that the suicidal patient is quite different in each of the three Scandinavian countries, and these differences reflect vastly different cultural attitudes and psychosocial pressures. That these pressures are exerted on everyone in the culture is confirmed by the study of nonsuicidal patients and nonpatients as well.

A performance type of suicide is prevalent in Sweden; among the men, success or failure has a life or death meaning. They have rigid performance expectations, with great self-hatred for failure. The dreams of the male suicidal patient are of frustrated ambitions and barely missed opportunities.

This performance suicide is set in a matrix of characteristic Swedish affectivity problems. For example, the Swedish tendency is to handle anger through withdrawal and detachment, and there is an apt Swedish idiom, *tiga ihjäl*, meaning to kill somebody through silence. The adult male often tries to deal with personal emotional difficulties by an intense concentration on success at work, and his work often develops a driven, pleasureless quality.

As an apparent consequence of detachment, repressed anger, and dampened affectivity, the feeling of being already dead emotionally is pervasive among the Swedish suicidal patients. Life may be seen as a living death, and even afterlife fantasies express little hope of a change in this situation. Similar feelings of emotional lifelessness are widespread among Swedish nonsuicidal patients and nonpatients as well. Swedish literature reflects this preoccupation with life as a living death: Lagerkvist, Sjöberg, Halström, Dagerman, and a host of other Swedish authors have produced perhaps the world's most prolific and sensitive literature on death.

Both the performance concern and the affectivity problems have their origins in childhood. The Swedish

child, particularly the boy, is taught not to show too much feeling. Emphasis is placed on the child's ability to be reasonable and unemotional, even in disturbing situations. Children are not allowed as much direct expression of anger toward parents or siblings as American children are. To be *tyst och lugn*—that is, quiet and calm—is something of a Swedish ideal, and the child learns early to treat strong emotion with detachment.

Equally important in its effect on affectivity and performance is the early mother-child separation that takes place in Sweden. The Swedish mother, in contrast to the Danish mother, wants an independent child as soon as possible and is pleased with evidence of his self-sufficiency. This is true whether she works or not. As expressed by one Swedish child psychiatrist, the mothers just don't seem to enjoy their children very much; they don't get the same pleasure from their children, whether caring for them or playing with them, as do Danish and American mothers. This early separation has serious consequences for the child's emotional development and is the source of much repressed anger. Furthermore, from the child's earliest age, Swedish parents are more interested in how he compares with other children than are Danish parents. Thus, he learns to use his performance both to bolster his self-esteem and to appear more lovable to his parents.

In Denmark performance suicide is conspicuously infrequent. Frustration of dependency needs through separation, loss, or abandonment is the situation most often responsible for precipitating suicide attempts. This dependency loss type of suicide reflects a particular and unique Danish dependency constellation. The Danish child is cuddled, fondled, and encouraged to remain dependent to a far later age than are children in Sweden or in the United States. Danish mothers are likely to boast of how well their children look, how well they eat, and how much they weigh. They are far less likely to boast of those activities or qualities in the child that may in any way separate him from the mother: how early the child can walk or talk or do things for himself.

In addition, the child's aggression tends to be curbed even more than in Sweden. It is in a sense the price he pays for his dependence. Danish children often seem like angels to Americans, and American children may seem like monsters to the Danes. Nor is it usual for aggression on the part of Danish children to be checked directly. Arousing the child's guilt ("Look how much you have hurt Mama") is the vastly predominant form of discipline in Denmark. The Danes grow up as masters of the ability to arouse guilt in others, and Danish suicidal patients make use of this ability to a marked degree.

Of course, this curbing of aggression heightens the dependency of the Dane. Dependency and passivity are usually related, and Danish adult patients show degrees of dependency and passivity that are seldom

observed in patients in Sweden or in the United States, even among those labeled as passive.

Dependent fantasies and dreams of a pleasant reunion in death are much more characteristic of Danish than of Swedish suicidal patients. It is interesting that the Andersen fairy tales reflect this theme over and over. The Little Match Girl, while freezing to death in the cold, lights her matches and sees the image of her grandmother, the only person who ever loved her, with whom she is reunited after her death. The Steadfast Tin Soldier can be united with his ballerina doll only in the fire that destroys them. It should be pointed out that this is by no means the universal theme of all fairy tales. Consider only that in the Andersen tales, competition and superhuman performance are not depicted as important; neither giants nor dragons have to be killed by the hero in order for him to be successful.

The Swedish tales, by contrast, are often adaptations of German tales; the emphasis on performance is primary, and the winning of the heroine at the end may be incidental. If the heroine is not won, the reaction is not one of abandonment or loss but one of poor performance, for which the individual gives himself, so to speak, a low mark in love. In the Danish tales, the individual is lonely and abandoned without love and is particularly sensitive to its loss.

While the reasons for the low Norwegian suicide rate cannot be dealt with here, it is worth noting that despite its low rate, rural Norway serves as an excellent laboratory for the study of one type of suicide. This may best be described as a moral type, based on a combination of aggressive antisocial behavior and strong guilt feelings, with the entire pattern cast in a puritanical setting. The seaman, mentioned earlier, who felt he deserved to be burned in hell for not leading a more Christian life was a Norwegian who typified this pattern.

All three suicidal patterns are encountered in the United States; but as this is a nation of subcultures, the multiplicity and mixture of patterns here make the task of identifying them extremely difficult. Sweden, Denmark, and Norway—small in population and related, but distinctive in culture—give the opportunity to observe their patterns in a pure form and under their original formative conditions. Limiting the variables simplifies identification of the same phenomena in the United States. In other words, the Scandinavian countries supply a vast clinical laboratory for studying the psychodynamics of suicide.

Other countries offer similar possibilities. Japan has long attracted attention because of the dramatic, ceremonial quality of such forms of institutionalized suicide as *hara-kiri*. Institutionalized suicide is negligible in modern Japan, yet the Japanese suicide rate remains among the highest in the world. To what extent is the present rate in Japan influenced by past tradition? To what extent by the breakdown of tradition under the influence of rapid Westernization? When the answers

to these questions become available, they will add much to our knowledge of suicide.

Subcultures within the United States also require specific study. For example, urban suicide among Negro men of 20 to 35 years of age is almost twice as high as that for urban white males in the same age group. At older age levels, the white rate is significantly higher than that for Negroes. This suggests some differences in motivation for white and Negro suicide, and work currently in progress indicates that such is the case.

Prevention

Although most social institutions have advantages, there is also a price to be paid for them. It seems probable, for example, that the early mother-child separation in Sweden and the related emphasis on the child's level of performance stimulate achievement but handicap emotionality. However, an awareness of disadvantages does not imply an immediate recommendation for change. It is easier to learn the effect of established institutions than to foresee the consequences that change may bring. Psychosocial studies can illuminate the relationship between a nation's institutions and the character of its people. Properly used in cross-cultural research, they may help us make more intelligent evaluations of social alternatives.

Currently, community efforts to prevent suicide have focused on special organizations or centers where the potential suicide can seek help. The center usually has a telephone number that can be called day or night. An attempt is made to persuade the caller to come in for evaluation. This may be followed by some form of counseling, or occasionally the patient may be seen on a more sustained basis, usually by a caseworker. More often, evaluation is followed by referral to another agency, where the individual may receive similar aid. Some of these centers have facilities for evaluating and referring a small number of patients who have been hospitalized following suicide attempts.

So far, such centers have not had any effect in reducing the suicide rates of the communities utilizing them. There seems to be good reason for this. The people calling such centers do not constitute the crux of the suicide problem. Only a small minority have made suicide attempts. Although the majority are acutely troubled, suicidal ideas are often only a minor part of their picture. Certainly every possible psychiatric hospital should have outpatient facilities permitting such individuals to receive immediate attention. The prevention centers, although they attempt this activity, give the illusion of doing something more significant and specific for the over-all problem of suicide. Probably their most important function has been to dramatize for the community the problem of suicide.

If the goal is the reduction of the number of suicides, a more probable area of hope lies elsewhere. Since, as mentioned earlier, 60 per cent of the actual suicides have histories of prior attempts, concentration on selecting for treatment the serious risks among the sui-

cide attempts is necessary. Unfortunately, as matters now stand, the majority of these eventual suicides, after brief hospitalization, are sent back into the community without any provision for subsequent treatment. If, hypothetically, a program for treating all the most serious risks among the attempted suicides were established throughout the country, it might mean treating 5,000 to 10,000 new cases a year—a large number, but far more workable and far more meaningful than the literally millions of diverse calls that would be made were the current suicide prevention organizations projected on a national scale.

In discussing the treatment of the individual suicidal patient, one should keep in mind the fact that such patients run the gamut of psychiatric entities from nonpsychotics to advanced schizophrenics. Their ultimate prognosis is, of course, related to their underlying personality structure. It is, however, often possible to diminish the likelihood of suicide, even where this structure cannot be altered.

There are no reliable signs or symptoms for distinguishing the depressed patient who is imminently suicidal from one who is not. The psychiatrist's ability to evaluate all but the most obvious situations is dependent on the contact he can establish with the patient. Of the different types of patients discussed here, probably the most difficult to contact are those who see themselves as emotionally already dead. They are characterized more by apathy than by depression, and they are cut off from contact with their own emotions, as well as the emotions of others. This group contrasts sharply with the patients in whom a more truly depressive aspect is predominant, who often want help and who can be rather readily involved in therapy.

A knowledge of the psychodynamics of suicide is, of course, central to any therapy. It is hard to conceive of any successful psychotherapy for the suicidal patient that does not deal with his suicidal dreams, wishes, and fantasies. When the patient or therapist avoids discussing such material, the situation is far more dangerous.

The treatment of suicidal patients involves a certain amount of necessary risk. Psychiatrists have often avoided such patients out of a reluctance to assume the responsibility. Although a certain number of suicides, in and out of hospitals, occur despite treatment, the therapeutic results among the suicidal patients who want help or are at least open to the possibility of receiving it are encouraging enough to justify more effort in this direction.

Suggested Cross References

For further discussion regarding the dynamics of depression, see Chapter 17 on affective reactions, which contains sections describing the various psychotic depressive reactions, and Mendelson's section on neurotic depressive reactions (Section 24.2). Sociological and cultural determinants of behavior are further discussed in Sections 4.2 and 4.1, respectively. The following

section on psychiatric emergencies contains additional discussion of suicide.

33.2 OTHER PSYCHIATRIC EMERGENCIES

JACK R. EWALT, M.D.

Psychiatry and the behavioral sciences have much to contribute regarding management of individual crises. The ability to deal with crises depends, in part, on the fact that the problems brought to a professional are usually those occurring in his own socio-economic group—upper middle class—and principally involve persons of his own culture. Since much of the psychiatrist's knowledge of human behavior centers around the Western middle class culture, more research is needed in methods of handling crises in backward and uneducated cultures.

Group crises constitute another area where there is a need for more information. Some knowledge has been gathered about coping with group crises in the United States, but it is unwise to apply our standards of behavior and morality to the aggressions of other cultural groups and nations.

However, no attempt is made in this discussion to present the subtle dynamics of crisis situations;

rather, this section presents descriptive information about recognition of *individual* crises and methods of management that have proved effective in particular cases for particular investigators. In addition, this section deals with methods of meeting psychiatric crises based on ego decompensation and with causes and emergency management pertaining to patients with long term mental illness and to basically normal individuals.

Crisis is manifested in many ways, most often via anger accompanied by varying degrees of aggressive behavior, severe anxiety accompanied by weeping, running, temporary states of confusion, and suicide attempts. Emergencies occur when an individual is faced with a situation beyond his particular adaptive capacity at a particular time. A person with considerable ego strength can cope with more stressful situations than someone with little ego reserve. Furthermore, a situation that is stressful for one person may not be so for another.

Many psychiatric emergencies are caused by anger, which represents a patient's response to affronts to his dignity or infringements on his rights. A large number of incidents occurring in mental hospitals are precipitated by rudeness from employees or by a conscientious employee's attempt to enforce irrational and insulting regulations. For example, patients are often required to surrender their personal belongings, including wedding rings and dental plates, when they are admitted and subsequently are refused use of a telephone or free access to visitors. Such treatment is offensive to all patients, and some become sufficiently angry to start fights or destroy furnishings. Anger of ward personnel toward co-workers and administrative demands or over a personal matter can be responsible for the arbitrary treatment of patients—behavior that patients may answer with disturbances of their own.

All people, including psychiatric patients, lose control of their behavior more easily when they are fatigued. Thus, while panicky escape efforts, angry outbursts, and bouts of weeping may be the manifestations of ego decompensation, the required treatment in such cases is rest and food, not psychotherapy. Also, alcohol ingestion may precipitate violent behavior in persons whose poor control stems from a character disorder or mental illness. In general, any situation or condition that is stressful may precipitate an emergency state in patients or in normal persons who are already bearing the maximum anxiety that they can effectively handle.

In any emergency situation it is necessary to determine, insofar as possible, what the patient is accomplishing or attempting to accomplish by his behavior. A patient who is disturbed or confused often responds positively to a question that pertains to his feelings and situation. A query such as, "Why are you so angry?" may elicit a sensible reply; conversely, a demand such as, "Now, now, control yourself,"

often compounds the difficulty. Most patients recognize a sincere desire to understand their viewpoints, and even very disturbed patients may become cooperative enough to discuss their plights.

The impulse to do something and the pleas of family or ward personnel for help often foster precipitous action, such as manual restraints, parenteral sedatives, or isolation. For one patient, manual restraints may represent security and protection from his own acts; for another, these restraints may represent a sexual or murderous assault. Similarly, sedation may mean relief, or it may seem to be an attempt to kill. With the patient who is in a turmoil state or who has just attempted suicide, prescribing treatment before some understanding has been achieved is indeed dangerous.

The cardinal principle is to find out what is going on—preferably from the patient. If the patient is too uncooperative, it becomes necessary to ascertain the cause of his troubles from informants or to deduce them from the circumstances that precipitated the emergency.

Acute Nonpsychotic Syndromes

Anxiety and panic (including fugues). For all human beings there is a limit to the tolerance of anxiety; when it is reached, some may react in a primitive fashion via attempts to escape. Classic examples are individuals who start panics in theatres at the smell of smoke or the cry of "Fire" and people who precipitate confused retreats in battle by panic and flight to the rear. Not so dramatic but far more common are the cases of students who respond to dormitory life or to the stress of examinations by entering an anxiety state with confused, disoriented, and psychotic type of behavior. In Army training camps, boot camps, and similar institutions, such persons appear to be schizophrenic because of the degree of decompensation and temporary regression. Similar responses are seen following natural disasters such as hurricanes, explosions, and earthquakes.

In certain individuals, a chronic stress situation may produce a severe anxiety reaction, characterized by dissociative phenomena and fugue states, in which the patient may wander off in a confused and disoriented manner. The majority of such patients respond to such supportive treatment as talking, rest, sedation, and, where indicated, food and fluids.

Some persons in early phases of anxiety or panic states appear to be having acute schizophrenic attacks; indeed, this actually may be the case. They become anxious and panicky with the first acute decompensation but later settle into one of the more classic types of acute schizophrenic disorders. However, some patients who have had an acute reaction subsequently become entirely compensated, showing no further evidences of decompensation or intolerable anxiety until a future combination of stresses again proves too demanding for their egos. On the other

hand, a few persons, particularly those who have been in some external disaster—such as an explosion, fire, prolonged combat, or other dangerous situation—may develop a traumatic neurosis in the strict sense of the word if they are so predisposed.

Homosexual panic. This reaction occurs in latent homosexuals who are exposed to barracks or dormitory life for the first time and whose already overburdened egos render them incapable of coping with the situation. The stimulation of gang showers and the horseplay common in all-male residential arrangements may constitute threats that the latent wishes will become conscious. Fear of the imminent breakthrough may result in the individual's becoming confused, sometimes to the point of hallucinating, and making agitated attempts to escape. In an acute phase, it is impossible to determine with any degree of assurance whether ameliorating the stress situation and bolstering the ego through reassuring human contact, sedation, and rest will cause the phase to subside. Nonetheless, persons undergoing homosexual panic should be removed from the stressful situation, cared for—if possible, by personnel of the opposite sex—and, after much reassurance and talking, given sedatives. Oral sedatives are preferable, since the patients sometimes interpret "needle work" as some type of homosexual assault. Similarly, while talking to such a patient, one should be wary of touching him prior to gaining his confidence. The attempt to grab and hold such an agitated patient can often result in a violent outburst because of his feeling that he is being assaulted.

Postconvulsive confusion. After seizures, many patients develop periods of confusion and may become quite combative or excited. Following a seizure, an individual who is unconscious but resting quietly and breathing freely should be turned over on his side, with his face in a slightly downward position, and should be left alone. Care should be exercised to prevent his falling from the bed; if attendants are not available to watch the patient, he should be placed on a mattress on the floor. Because attempts to restrain the patient in the bed with wrist bands usually result in disturbance and thrashing about, the floor is more effective. If such patients become excited and want to run, they must be restrained. Usually, if they are restrained and reassured they can be quieted rather quickly. If not, medication, such as pentobarbital (Pentothal sodium), is indicated to help them through the confused state.

Occasionally, an *epileptic furor* produces a prolonged period of excitement that requires more heroic measures; but again, anticonvulsant medications and quick-acting sedatives are the treatments of choice until these states subside. Sometimes electric shock therapy produces an almost miraculous cure for an epileptic furor, but it is no small task to hold a patient still long enough to apply the electrodes, administer the Pentothal and whatever relaxant is being

used, and administer treatment without damage to the patient. With the wide spectrum of quick-acting sedatives available, including Pentothal and intramuscular chlorpromazine, it is doubtful that use of shock is justified. In theory, one of the barbitals compounds is preferable to chlorpromazine; the barbitals tend to be anticonvulsant, but the chlorpromazines may aggravate the convulsive state. In practice, however, this distinction does not seem to be important. The major emphasis in the treatment of postconvulsive disorders is on protecting the patient and his surroundings until the condition subsides.

Aggressive behavior—individual and group. These emergencies, in which behavior is irrational and dangerous, may start with something as simple as a family squabble and grow into an outbreak of mob violence or community anger at some real or imagined insult to an individual or group. Talking at an unhurried pace is the best way to manage emergencies of this sort. If the person attempting to deal with the situation does not allow himself to become threatened or excited, his inquiring into the cause of the anger and offering the promise of opportunities for discussion—but not guarantees of an irrational solution—can often quiet such a situation. Two examples of such cases follow.

A schizophrenic patient became very aggressive, armed himself with a pair of shears and a table leg, stood in the rear of a small private room, and invited onslaught by any and all. Rather than complying—as by rushing him, protected by a mattress—the staff sent someone in alone and unarmed, instructed to keep carefully out of range, to talk to him about why he was so angry. The fact that the patient was psychotic was ignored for the moment. The cause of the patient's attitude was quite a simple one; he had been denied the right to use the telephone to call his father, who had promised to send him money for cigarettes and had failed to do so. It was agreed that, if he disarmed himself and behaved in a way indicating his competence to use the phone, he could do so. The physician talked with him briefly in a manner that reassured the patient, and the agreement was carried out.

A large squadron of police, armed with machine guns and other weapons, surrounded a building in which several mentally defective, delinquent boys were rioting. The boys were allowed to carry on the riot within the institution for a reasonable period of time until they had become somewhat fatigued and bored. The apparent leader was called to the window and was asked what the boys hoped to accomplish by this behavior. He stated that they wanted a hearing. They were promised that, if they came out peacefully, they would be locked up in a maximum security unit and would have an appearance in court the following day for their destruction of state property. They were specifically told that at the hearing they could say anything they wished. Probably because of the implied punishment, the group believed the promise, and the riot was over in a matter of 5 or 10 minutes. The promise was carried out.

Acute Brain Syndromes

Alcohol intoxication. Perhaps the most common cause of psychiatric emergencies is alcohol intoxication—the disturbed drunk. Some people do not know how to drink, and after a few or many drinks they become obnoxious, aggressive, or panicky. Some want

to drive automobiles, which is indeed an emergency. The use of sedatives for such patients must be approached with caution, for there is danger that the alcohol not yet absorbed may produce a lethal mixture if combined with a heavy dose of intravenous or oral sedation in the form of barbitol or one of the tranquilizing drugs. However, if some type of intervention seems necessary, it is probably best to use some form of tranquilizer.

With such a patient it is very important that he be nursed and kept lying on his side. It is not uncommon for patients who have been drinking excessively to enter a semicomatose state, vomit, aspirate emesis, and die. Allowing the patient to stay alert and walk around, if he is not too destructive, is desirable. If the patient is allowed to talk and if he can be reassured and cajoled, his extreme behavior often subsides. At times, the disturbance is such that it is necessary to place the patient in some type of seclusion or send him to jail. The latter procedure should be avoided if possible, since nursing care in jails is often not good, and there is the danger that he will pass out on his back and aspirate emesis.

Drug intoxication. Some psychotomimetic drugs—such as lysergic acid diethylamide (LSD), mescaline, and marihuana—may produce acute delirious episodes in which individuals become disturbed, overactive, and aggressive. Strangely enough, these drugs are less apt to produce emergency states than alcohol, but, if they are ingested by a group and a member of the group becomes aggressive, it is quite possible that others will follow suit and that some type of emergency will develop. Perhaps a greater danger is that patients in a toxic delirious state may wander off and injure themselves in a traffic accident or in a fall from a window or down a stairwell. The management of these cases consists of the intramuscular administration of phenothiazine and the provision of a special nurse or companion to keep them out of difficulty until the toxic effect subsides. Fortunately, toxic effects of these drugs are usually short-lived, except in those patients who became psychotic after ingestion of one of these compounds.

Overdoses of barbitals or bromides seldom produce acute excitement states, but they may produce poisoning. The treatment is to send the person to an emergency room where gastric lavage and some type of dialyzer or artificial kidney are available and where artificial respiration can be maintained until the toxic substances have been removed from the blood by dialysis.

Delirious episodes. One of the more common psychiatric emergencies occurs in those patients suffering from some type of somatic or postoperative toxic state. These states are usually manifested initially by the patient's becoming apprehensive, muttering incoherently, picking at the sheets, or appearing generally anxious and restless. Nurses should be alerted to these symptoms, and the medical staff

should be prepared to take emergency measures. The best possible treatment is to keep such patients in a brightly lighted room, to remove the toxic substance as quickly as possible, and to assure adequate hydration while avoiding water poisoning. The use of dehydrating solutions may be indicated if the toxic state is due to conditions which tend to cause fluid retention. Shadows, noises, or unexplained actions on the part of the nursing or medical staff may produce panic in these patients. Some, in attempting to run from their apparent assailants, may jump or fall from a window or down a stairwell and be seriously injured. The best treatment is a bright room, a sensible nurse who can reassure the patient, and direct dealing with the patient. He should be told that he is imagining things because of a delirium and that he will recover. Medication is to be avoided if possible. If the patient becomes unmanageable, parenteral injection of one of the more potent tranquilizers (chlorpromazine or an equivalent drug) may be used.

Suicide

The prevention of suicide, especially when the patient makes threats or minor attempts at suicide, presents one of the most common psychiatric emergencies and, in terms of clinical judgment, one of the most difficult. Physicians, social workers, health nurses, clergymen, and others dealing with family problems and helping people to cope with behavior must at some time make decisions about the seriousness of suicide threats. Everyone is familiar with cases of the hysterical housewife or inadequate husband who manages spouse and family by sighs and such statements as, "I'll be better off dead; I'll just kill myself," which the family eventually learns to disregard. Also familiar is the individual who becomes depressed, quietly puts his affairs in order, and, without prior discussion, successfully commits suicide.

Individuals soon learn that suicide threats are potent anxiety producers and they use them to manipulate others. The husband who has strayed may be brought back to the "straight and narrow" by a wife who makes an abortive suicide attempt. The adolescents in an open ward hospital who feel that their turmoil and discomfort are not receiving sufficient attention can quickly gain a great deal of notice by breaking a window and slashing their wrists with the fragments. The problem lies in deciding how seriously one should take the threats.

As a general rule, such threats should be taken seriously during the initial contacts with the person who makes them. Whether it is a manipulative gesture or the announcement of a genuine attempt to commit suicide, the threat is a signal or indication that the person is asking for assistance. Shneidman and Farberow have dubbed it "the cry for help." From the most manipulative to the most fatally sincere, every suicidal individual needs someone to give him attention and to talk with him. If the person telephones,

he should be permitted to ventilate and encouraged to tell how he feels and what kind of help he would like; when contact has been made, an appointment should be arranged. In no instance should the person be cut off, nor should he be asked to promise not to commit suicide. The approach should be one of "Let's talk it over" and "Let's put it off until we talk about it." After the physician knows he is being taken seriously, he can point out that the opportunity for suicide always exists and that it is desirable to discuss the situation before this step, from which there is no return, is taken. In most instances an individual can be persuaded to come to the physician's office or emergency room or can be persuaded to allow the physician to send someone around to escort him to the hospital.

Another type of suicidal patient is the person who is known to be depressed or suicidal and who, after calling his physician and being unable—for any of a variety of reasons—to reach him, commits suicide because he feels rejected. The physician who is carrying patients who are suicidal must make special arrangements with them—and, more importantly, with himself and his secretary—so that these patients can reach him by telephone at all times or so that they clearly understand that there are particular times at which he cannot be reached. Such patients should be allowed to call the physician at home. If he is to be away on a trip, they should know where he is and what means of travel is being used. Such patients usually understand that there may be times when they will be unable to reach him. Patients like to feel that the physician is dependable, reachable, and concerned about their problems and that he understands that they are, at times, under more pressure than they can bear and, therefore, need to be in touch.

Too much reliance should not be placed on the procedure of hospitalization. The hospital offers as many or more opportunities for suicide than do public streets. If the patient is placed in the hospital for a suicide attempt, he must be under continual observation; otherwise, the staff is placing too much reliance for prevention of suicide on the patient's belief that the act of hospitalization will protect him from himself.

It is often not possible to judge whether a suicide threat is genuine or manipulative, and one cannot be sure as to how significant the difference between such threats is. All threats are manipulative in the sense that the patient is seeking attention and at the moment believes he needs it. Whether he will actually make a serious or successful attempt probably depends on how angry he is with others; how rejected and lonely he feels; and how hopeless, unworthy, and desolate he feels.

Certain clues are helpful but not infallible. Persons who have tended to act impulsively in the past and have perhaps been diagnosed as having character disorders may well commit suicide in an impul-

sive manner. Patients who are drinking heavily or using drugs indiscreetly may also commit suicide either intentionally or accidentally by overdose of drugs during periods of confusion. Persons lacking support or a fabric of supporting friends, job, and place in the community are also vulnerable. Persons who have recently suffered reversals in their personal lives, health, or social and business dealings—that is, those who have sustained tremendous blows to their self-esteem—are great risks. In general, however, the only safe rule is to take every suicide threat seriously until there has been established sufficient contact with the patient to permit an understanding of what is going on and until he can be convinced of the physician's concern with and appreciation of what he is undergoing.

Chronic Brain Syndromes

Patients with chronic organic brain syndrome of whatever cause share a set of symptoms that may produce a psychiatric emergency. Most patients with organic disease of the brain are irritable and have a tendency toward explosive outbursts of rage or temper tantrums. Irritability or an outburst of rage is only one part of the general emotional incontinence, which is more commonly manifested by weeping for little or no obvious cause. Temper outbursts of patients with chronic organic brain syndrome are usually provoked by some environmental event that they interpret as an affront to their dignity or that reminds them of their growing age and decrepitude. For example, one rather elderly gentleman with beginning senile dementia required hospitalization because he became violently angry with his wife and chased her with a hatchet because of her admonitions about his rather unkempt appearance. While in the hospital for observation, he became equally angry with first the nurse and later the physician who inquired as to whether or not his bowels had moved. He later said he regarded such inquiry as an affront to his good sense and stated that he might be crazy, but he had sense enough to know when his bowels needed to move.

The unpredictability of these outbursts, precipitated by trivial external pressures, makes these patients dangerous if they are prone to violence, and they should not be allowed to possess guns or other weapons.

The emergency is treated by controlling the patient's behavior until the violent outburst subsides. Good nursing care, the presence of a reassuring physician, not making an issue of what the patient is angry about, and encouraging him to explain why he is angry often result in decompression of his ire and a return to a more reasonable attitude, often in a few minutes. During the period of anger, such a patient is dangerous if armed, and, if possible, a confrontation should be avoided until he has recovered control of

his emotions. Some organic patients also become paranoid and vindictive.

A second type of emergency in chronic brain syndrome is the suicide attempt. Patients with chronic organic disease may become depressed, lonely, and suicidal. The problems here are not different from those of suicide in general except that the suicidal attempt may be impulsive after an aggressive act on the part of the patient or after some other event that reminds him of his ego losses. The most common cause of suicide in the chronic organic state is the result of loneliness, loss of self-esteem, and feelings of worthlessness, neglect, and of life being without meaning.

A third type of psychiatric emergency seen in chronic organic brain syndromes is that caused by the patient who wanders away from home or hospital and becomes lost. In mild climates and in good weather this is not a major crisis, as the confused and wandering person is often assisted by the police or by some other person who helps him reestablish contact with his family. In cold weather or in sparsely populated areas, where the person can suffer from exposure, the wandering patient can become an emergency. The solution to this problem is prevention. If a person is known to become confused and restless, he should be watched. If his home and family lack resources to care for him, he should be placed in a boarding or nursing home that has adequate facilities.

Homicidal and Assaultive Behavior

Violence in terms of gangs, riots, and national aggression continues to plague the world, but individual homicidal behavior by psychiatric patients seems to be decreasing, due to wider use of tranquilizers and increased understanding of how to handle their interpersonal problems. As stated earlier, most violent behavior by mental patients is the result of anger, which is common to all mankind, rather than the result of mental illness as such.

One now rarely sees major assaultive behavior or homicide due to paranoid delusions or catatonic excitements, principally because techniques for the management of such patients have been learned. These techniques include listening to their delusions, helping them back to reality, and bolstering their impulse control with tranquilizers. Patients with paranoid delusions—particularly when temporarily confused by alcohol ingestion, unusual fatigue, or external stress—may feel threatened and thus take retaliatory action. The well organized paranoid who feels that some other person is plotting against him in order to deprive him of an invention or to cheat him of an inheritance is more apt to take legal measures than direct violent action. Usually, only when such a person recognizes that legal outlets are not available to him will he resort to violence. In most cases, however, discussion with a trusted person results in subsiding of the symptoms. Trust is not established by agreeing with the patient's delusions. In most cases, it should be pointed out to the patient that what he says sounds paranoid.

Nevertheless, he should be listened to, and an attempt should be made to help him understand what the particular delusional system does for him.

It may be necessary, during the acute emergency state, to hospitalize the patient, but care must be taken not to make the hospitalization too coercive or too restraining, lest this precipitate the homosexual features of a panic. Usually, when a patient is in a psychotic turmoil and is very apprehensive and fearful, his physician or an experienced nurse who understands fearful patients but is not rendered anxious by such manifestations of violence can bring calm to the situation. Asking the patient, "What are you afraid of?" or "What are you angry about?" or, if it seems more appropriate, remarking, "You are very angry," or "You are afraid," or "I wonder if you would like to tell me about it?" can be the wedge for the patient's relinquishing action in favor of talking. One must be wary of grabbing a patient or laying hands on him until it is certain that the patient *wants* to be controlled to protect himself from his impulses.

Serious aggressions that could result in homicide are of two main types. The first occurs when a person feels aggrieved without hope of redress and quietly and skillfully plots a murder based on paranoid delusions or grievances. Once this type of patient conceives the idea of homicide, he becomes fixed on it and needs careful supervision until a combination of drug therapy and conversation helps point out the futility of homicide and the self-destructive aspects inherent in such plans. A different quality of violent behavior that may result in homicide or serious injury is seen in panic reactions motivated by fear and rage over immediate circumstances. The majority of these probably contain some degree of homosexual panic and the feeling that people are closing in to kill or mutilate the individual. The patient strikes out wildly and may shoot if he is armed. For example, in an attempt to escape from imagined persecutors, one patient commandeered a truck and killed an officer and a passerby in his wild operation of the vehicle. He was attempting to escape from what he thought was a group closing in on him for purposes of mutilation of his genitals. Although the first impulse is to rush in, grab, and restrain the person—and on exceptionally rare occasions this may be the only practical plan—usually a calm discussion by a person who is not made anxious by the violence results in the patient's quieting down and establishing a measure of self-control. Having determined the nature of the problem and having persuaded the patient to take medicine to make him more comfortable, the therapist can then carry out the management of the patient according to the basic difficulty.

Schizophrenic Turmoil

It is difficult to discuss emergency reaction without lengthy exploration of the management of schizophrenia. Some schizophrenics develop a panic reaction,

usually with strong homosexual coloring, elaborated by their paranoid projections. The general principles described earlier for the management of panic and rage apply here.

Catatonic excitement presents a slightly more difficult problem. Patients who have, by their catatonia, controlled their homicidal rage—the desire to demolish, incorporate, and destroy persons who fail to love them or give them the care and attention they want—sometimes lose control and have violent outbursts of aggressive behavior. Patients of this sort may, on occasion, be amenable to discussion with their therapists. Usually, if such a patient is in a good relationship with the therapist, violent outbursts do not occur. Outbursts are most likely to happen when no trusting relationship has been established or when the therapist has recently been lost. In some instances it is necessary to use physical restraint. Patients in this state often appreciate having someone grab and hold them and administer quieting medication, such as phenothiazine; they very often *want* to be controlled and to have assistance in managing their homicidal impulses. Confidence in the understanding of the physician and the ward personnel and in their desires and abilities to help is of great comfort to these patients. A case where such a gesture toward control proved sufficient follows.

A patient who was being cared for on an out-patient basis called and said he felt he was losing control and needed to be hospitalized. The hospital was notified to admit him, to allow him to stay as long as he felt necessary, and not to attempt to keep him. The patient reported to the hospital; after about 4 hours, he called the ward doctor and told him he thought he was ready to go. Following a three-way conference with the therapist, the patient was allowed to leave. About a month later, a similar call from the patient resulted in a second hospitalization; this time 18 hours passed before the patient felt he had regained control and requested discharge. In each instance, the patient was able to control himself following discharge, and, although there was some manipulation of the tranquilizing drug, there was no significant increase in dosage. In effect, the demonstration that there was a noncoercive resource readily available gave the patient sufficient support to renew his confidence in his ability to control himself and made hospitalization over a prolonged period of time unnecessary.

Paranoid schizophrenics sometimes become quite upset. However, the type of turmoil or emergency situation they manifest is often a homosexual panic. The difference between homosexual panic in a college boy and panic actions in a paranoid schizophrenic is not great. In dealing with the schizophrenic, one must be careful to use simple, concrete expressions and to avoid figures of speech or allusions that may be subject to multiple interpretations. Otherwise, the principles presented earlier also apply here.

The general principle of handling paranoid patients is to be trustworthy and honest with them. The following incident illustrates this.

A distressed young man burst into the office of a psychiatrist, sat down, and stated that he needed to talk. He immediately embarked on a long and typically paranoid tirade about the police, the neighbor's children, and fears of homosexuality.

After 35 minutes, he stopped and calmly asked, "Now what do you think of this?" The psychiatrist's response was, "I think you are suffering from paranoid schizophrenia and should be in the hands of a good psychiatrist." The young man's anxiety, anger, and tension subsided, and he revealed that he was already seeing a psychiatrist but didn't trust his diagnosis, so he had sought outside consultation from another psychiatrist.

Any attempts to placate the young man and ease his delusional system would have made him more suspicious and distrustful. But the psychiatrist's statement, which apparently rang true, gave him confidence in his own psychiatrist and emphasized to him his need for treatment.

Sometimes irrational patients are not so irrational as some of the methods employed in handling them. Only respect for patients as human beings with thoughts, wishes, and sense of personal destiny—even though temporarily distorted by mental illness—can produce proper attitudes for dealing with them, both in and out of emergency situations.

Manic-Depressive Emergencies

Manic excitement. There was a time when overactive and manic patients constituted one of the major headaches for hospital administrators. Today, with proper management, these attacks are short-lived and cause little disturbance. If emergencies do occur, they usually involve a manic patient's being arrested for operating an automobile too rapidly, for piling up debts, or for getting into disgraceful situations with members of the opposite sex. Most manics are agreeable, although they can become irritable and combative, and their episodes are usually of short duration. If patients refuse to enter hospitals voluntarily, they should be admitted on temporary papers and treated with appropriate tranquilizers. It has been the experience of many investigators that, if these patients are secluded from other disturbed manics, are placed in a general ward population, and are given special nursing attention and adequate tranquilization, their overactive and socially obnoxious behavior can be controlled within 3 or 4 days, sometimes less. Manic patients, in general, tolerate larger doses of sedatives than do patients of other types, and the stronger tranquilizers available are the medications of choice. If the patient does not cooperate in taking oral medication, it should be given via parenteral injection.

Depressive emergencies. Suicides are the most common emergencies among depressive patients. Sometimes patients are seen in whom malnutrition, attempts at self-mutilation, or acute exhaustion from excessive agitation represents an emergency. Drastic intervention is indicated at such times; properly administered electroconvulsive treatment is still the safest and most effective way to handle this type of emergency state.

Emergencies with Adolescents and Children

The most common emergencies with children are accidents and poisonings. Pediatric services and poi-

soning centers know that some children undergo such experiences repeatedly. In these cases the psychological development of the child and the home situation bear investigation. This can be initiated gently by the pediatrician. If the real pathology is found to be within the child or his family, the case is best referred to a child psychiatry clinic. The point here is that psychological or psychiatric aspects of the most common childhood emergencies should not be neglected.

The temper tantrums of small children constitute crises, the disastrous effects of which can be averted by proper handling. A child has not yet learned to experience anger, distress, or sense of loss appropriate, from an adult point of view, to the nature or degree of the insult or loss. Children, especially those under the age of 7, tend to become as angry over minor insults or deprivations as over major ones—an all or none reaction. In managing situations, the parents should realize that the child may be as upset because he was not allowed to accompany an older brother to a Boy Scout meeting as he would be over the permanent loss of the older brother. Children should not be punished or unduly reprimanded because they seem extremely angry or aggrieved at what seems to the parents a trivial situation. Correct parental attitudes are expressed in such statements as, "I know you are very angry and upset about this, but there is nothing you can do about it, and your brother will return later," or "When you are old enough to go to Scout meetings, you can go by yourself, and he will be too old," or some other statement that points out the reality of the situation to the child but does not punish him for being so angry.

Emergency situations with adolescents are far more common than with children or at least may take forms that are more appropriate for psychiatric attention or intervention. Sometimes adolescent regression takes the form of emotional outbursts, so that they show some of the all or none response more appropriate to smaller children. Adolescents experience many tensions as they begin to establish their own identities, establish their own inner controls, develop a moral sense independent from that of their parents, and question and challenge parental authority. They experience a great deal of anxiety, sometimes referred to as the "adolescent crisis." At this time, one can expect violent outbursts of sobbing; rage; even acting out, such as injudicious operation of cars; suicidal gestures by the more unstable; violent sexual acting out; and serious delinquency, crime and experimentation with drugs, for example. Psychiatry introduces the possibility of another crisis: the adolescent runs the risk of being ignored or treated like a delinquent on the one hand or of being diagnosed as a schizophrenic on the other because, during periods of great anxiety and turmoil, he may indeed be psychotic for a few minutes or days.

Such adolescent turmoil reactions usually respond

rather dramatically to the establishment of a relationship with someone who understands the individual and regards him as a person with rights, privileges, and a certain amount of good sense. Physicians usually enter such situations during a family riot scene, in which people are weeping, yelling, and recriminating. A few minutes of this reveals the general flavor of the family relationship; the session is sometimes as formalized as a family conference and usually suffices for the first interview. Immediately afterward, the adolescent should have an individual interview with the physician, social worker, or nurse, depending on who is taking the major responsibility at the time. Again, words that are supposed to comfort, such as, "Now, now, everything is going to be all right, but control yourself," or "This kind of behavior will get you no place," can only increase the adolescent's feeling that he is being misunderstood and outraged. Instead, statements or questions that convey the therapist's wish to understand, such as, "Do you want to tell me what's going on?" or "What is it you're so upset about?" or "You seem very angry, could you tell me what happened?" will produce a flood of information.

Adolescents tend to appreciate a person who seems to understand, and they form attachments and begin to confide in such an individual much more readily than adult patients do. One should remember, however, that adolescents are very wary and suspicious of adults. One must be particularly careful to avoid being "in cahoots" with the parents. This is especially difficult when the adolescent is the child of a colleague or another physician or a person of prominence in the community. Psychiatrists may feel that they should try to placate the parents or carry out their wishes—that is, control the adolescent and make him behave—rather than attempt to understand the patient's point of view and assume the role of his ally or colleague. At times, such cases may seem to place the physician in opposition to the parents; this is a problem for the social worker.

Joint family interviews and family therapy often produce similar difficulties; a great deal of conscious thought and attention to avoiding partisanship with the parents and actually, when any doubt arises, siding with the child is of maximum importance in such situations. Acute emergencies with adolescents usually subside very quickly, often within a few hours, though they sometimes require a little longer. The more onerous problem then arises of working out the child's developing feelings of identity and enabling him to develop sufficient ego strength to cope with the world about him.

Suggested Cross References

In this section, psychiatric emergencies that occur in association with a wide variety of psychiatric disorders were discussed. For more detailed information regarding the specific disorders, see the discussions

of gross stress reaction (Chapter 28), traumatic war neurosis (Section 28.2), alcoholism (Section 27.3), addictions (Chapter 27), suicide (Section 33.1), delirium (Section 18.3), acute and chronic brain syndromes (Section 18.2), paranoid reactions (Chapter 16), schizophrenia (Chapter 15), and manic-depressive reaction (Section 17.1). PSYCHIATRIC TREATMENT

The primary aim of psychiatric treatment is to alter pathological behavior. Although the dynamics of human behavior are not completely understood, it is clear that all behavior, whether normal or pathological, is the result of highly complex interactions involving biological, psychological, and environmental factors. Thus, the physiology of the individual's brain, his developmental history, store of cognitive information, interpersonal relations, sensory input, and affective experience, as well as the characteristics of the environment with which he interacts, are included among the variables which will determine his ultimate personality and behavior.

The manipulation of these various determinants can result in significant changes in behavior. However, some of these behavioral determinants are manipulated more easily than others. For example, relatively little can be done to alter certain types of permanent central nervous system damage, or the pathological elements in a patient's critically important early developmental history, or some of the realistic limitations of his environment. On the other hand, other equally crucial behavioral determinants can be changed. Among these are distortions in the patient's perceptions and in his relationships with others, the chemical state of his brain, and certain irritating factors in the environment which tax his adaptive resources.

The psychiatric treatment techniques described in this Area intervene at various levels of human functioning to manipulate one or more of the accessible behavioral determinants. These methods may be classified accordingly as psychological, organic, or environmental.

Psychological treatment. The psychological treatment methods in current use include the various forms of psychoanalysis and psychotherapy, the behavior therapy techniques, and group and family therapy.

All of these methods share one common feature: they all attempt to modify pathological behavior by intervening on a psychological level.

The goals of psychological treatment range from relief of a specific symptom, such as bed wetting, to attempts at effecting fundamental changes in a patient's basic character structure and pattern of adaptation to important areas of living, such as work, sex, and interaction with other people.

Theoretical assumptions and techniques of treatment also vary considerably. Thus behavior therapy employs conditioning and extinction techniques which are derived from learning theory in order to relieve psychological symptoms. Other forms of psychotherapy and psychoanalysis rely heavily on the interactions between the doctor and patient to achieve the desired changes in behavior. This therapeutic transaction may involve the exchange of information as well as a highly emotional component. The emphasis in psychotherapy will depend on the diagnosis and the problems of the individual patient. Thus the primary goal of treatment may be to provide a corrective emotional experience with the assumption that this will facilitate the development of more adequate adaptive responses. In other cases, treatment techniques will focus on fostering the patient's insight into the nature and source of fears, wishes, conflicts, and perceptual distortions, which may lie outside conscious awareness, but which are assumed to underlie his pathological behavior.

In contrast to the emphasis on the one-to-one doctor-patient relationship which is the hallmark of the individual psychotherapies, group therapy methods make use of the operation of multiple interactions among the members of the group as well as between individual patients and the therapist. This procedure provides unique opportunities for the clarification and subse-

quent change of pathological interpersonal transactions, which are believed to contribute to many types of psychiatric disturbances.

The various forms of psychotherapy which are described in the sections that comprise Chapter 34, below, are useful in a wide range of psychiatric disorders. However, not all behavioral disorders can be treated effectively by the exclusive use of psychological therapy. Other treatment modalities are often used to supplement psychological treatment, and in some cases these constitute the major aspect of the treatment.

Organic treatment. Organic therapy may be defined as an attempt to modify or correct pathological behavior by physical or chemical means. The relationship between the physical state of the brain and behavior is highly complex and imperfectly understood. It is clear, however, that the various parameters of normal, as well as deviant behavior, such as perception, consciousness, affect, and the cognitive functions, may be profoundly affected by certain physical changes in the central nervous system.

Organic treatment of the psychiatric disorders is largely empirical. The underlying mechanisms by means of which a chemical or physical change in the brain produces an improvement of abnormal behavior has not as yet been completely delineated. Nevertheless, some of the organic therapy techniques have proved highly effective and may constitute the treatment of choice for certain psychopathological conditions. As such, they form an important part of the treatment armamentarium of the psychiatrist, and of practitioners in other medical specialties as well.

Description of treatment techniques, indications, rationale, and results of the organic therapies which are currently in common use are discussed in Chapter 35, below. Among these are the psychoactive drugs, the convulsive therapies, insulin coma treatment, and psychosurgery.

Milieu therapy. As mentioned earlier, environmental factors may exert a significant influence on psychological functioning. It follows, then, that the manipulation of the environment, which has been termed milieu therapy, may result in significant behavioral changes.

This theoretical orientation has produced specially structured hospital wards and schools, sheltered workshops, and day and night hospitals. Within these settings, milieu therapy refers to the effects on the patient of the hospital environment, the behavior and attitudes of the medical and paramedical staff, the group interaction among patients, and interactions between patients and staff. The concept of milieu therapy has also resulted in the organization of partial hospitalization procedures, whereby the patient is en-

couraged to participate in the community in a limited, graduated, and transitional manner and, concurrently, to derive the therapeutic benefits of day- or night-time hospitalization. Finally, milieu therapy also includes the therapeutic use of occupational and recreational facilities.

To a great extent, milieu therapy might be considered sociological in orientation. It is concerned primarily with the role of staff and patient and the structure of a ward community which is designed to facilitate the patient's recovery. The physical characteristics of the hospital, e.g., its geographical location, architecture, and the decor of the ward, may also contribute to the therapeutic milieu, and these variables are also considered to lie within the province of milieu therapy. Alterations in the environment, or social change, may also have therapeutic consequences, because social institutions are important behavioral determinants. This subject is discussed in the section on community psychiatry.

It should be emphasized that milieu therapy represents just one phase of the total psychiatric treatment program, which usually includes psychotherapy and/or some form of organic therapy as well. However, the application of the principles of the use of the environment as a therapeutic modality have greatly increased the range of effectiveness of psychiatric treatment.

Integrated treatment approach. Each of the therapeutic orientations, as well as each of the various techniques included under each rubric, is technically complex. For didactic purposes, the area on psychiatric treatment has been divided into four chapters. The first three deal with the psychological, organic, and milieu therapies, respectively. For the sake of comprehension a rather detailed discussion has been provided of technique, rationale, indications, and results of each form of therapy. The fourth chapter deals with evaluation of the effects of psychiatric treatment.

However, in everyday clinical practice there is no clear delineation between different treatment modalities. Patients with various diagnoses are treated with a combination of therapeutic techniques. The well trained psychiatrist is flexible in his approach and is skilled in the application and understanding of the indications for a wide range of treatment methods.

For amplification of the principle of an integrated and flexible approach toward psychiatric treatment, and for some appropriate clinical examples, the reader is referred to those sections in this volume which deal with specific clinical entities, such as schizophrenia, in which the treatment of choice involves the combined use of several of the therapeutic modalities.

Chapter 34

Psychotherapies

INDIVIDUAL PSYCHOTHERAPY

34.1 PSYCHOANALYSIS AND PSYCHOANALYTIC PSYCHOTHERAPY

ROBERT L. STEWART, M.D.

MAURICE LEVINE, M.D.

Introduction

The problems which bring people to psychiatrists for treatment are of two kinds: (1) those which seem to have their origin largely in the remote past of the patient's life, and (2) those which seem to arise largely from current stresses, both internal and external.

This simple contrast seems to be a statement of fact. But clinical study indicates that more complex configurations occur. For example, current external stresses may occur in combination with older problems, at times in a complementary series. Clinical observation also indicates that still another dimension should be added to the simple contrast: some patients, who have old but still active and unsolved problems, may arrange their lives unconsciously in such a way that they appear to be the victims of current external life situations. In such cases, an attitude of benevolent skepticism often makes it possible for the therapist to discern the outlines of the ancient past in the stereotyped repetitions in the current life difficulties and to see that the patient is playing a larger part than he recognizes in helping to bring about his misfortune.

Basic premises of psychoanalysis. The simple

division of emotional disorders into the two broad categories given above, incomplete as it is, provides a convenient starting point for a discussion of the facts and theory, the techniques of treatment, and the indications and contraindications of psychoanalysis and its near relative, psychoanalytic psychotherapy. This discussion might begin with the statement that, when a patient's problem stems mainly from the *past*, with relatively little contribution from the present, *psychoanalysis* might well be the treatment of choice.

During classical psychoanalysis, regressive patterns often appear in the patient's feelings and fantasies toward the psychoanalyst. These patterns, which are extensive but controlled, characterize the analytic situation and the analytic process. They provide the necessary ingress into the past, especially in the forms in which the past still survives in the psychobiological depths of each patient. Herein lies the value of psychoanalysis as the treatment of choice when the problem is considered to stem mainly from the past. However, the evocation of such regressive patterns is neither necessary nor desirable if the problems are predominantly current ones; psychoanalytic psychotherapy, in which there is considerably less emphasis on the study of archaic patterns of responses to the treatment situation, may then be the treatment of choice.

Theoretical model. Psychoanalytic theory is discussed in detail elsewhere in this volume. Briefly, *psychic events* (which are regarded as synonymous with "psychobiological phenomena," and "intrapsychic and interpersonal patterns") are conceptualized in terms of propositions which refer to their several dimensions. These propositions may be summarized as follows.

Genetic. Essentially, this is the historical dimension. The term refers to the complex interplay between the

inborn maturational phases and the environment of childhood, which includes inanimate, interpersonal, and cultural forces (and fantasies about them). Environmental forces may be strong or weak; they may be optimal or traumatic; or they may have still other impacts on the patient's psychological functioning.

Dynamic. The term "dynamic" refers to qualitative forces (jealousy, homosexual feelings, love, and rage).

Economic. This refers to the quantitative aspects of these forces, i.e., whether they are greater or lesser, increasing or diminishing.

Structural. Structural propositions are concerned with the schematized area of structure and function in which the specific forces operate. "Ego," "superego," and "id" are structural terms.

Topographical. This designates the relation of a psychic event to consciousness, that is, whether it is conscious, preconscious, or unconscious.

Biological and adaptational. These propositions take cognizance of man's state, at each period of his life, as a biological organism in constant interaction with his cultural, interpersonal, and physical environment.

Basic premises of psychoanalytic psychotherapy. Further discussion of this area requires a preliminary definition of psychoanalytic psychotherapy. Psychoanalytic psychotherapy utilizes the theoretical framework provided by psychoanalysis, as delineated above, with its genetic, dynamic, economic, structural, topographical, biological, and adaptational propositions. However, the therapeutic goals of psychoanalytic psychotherapy are different and less extensive. Moreover, in addition to interpretation, psychoanalytic psychotherapy uses various other techniques which are not, strictly speaking, part of the analytic model. Finally, while the interpretive techniques of psychoanalytic psychotherapy are similar in theoretical orientation to those of psychoanalysis, they focus on different dimensions of the patient's psychic events.

Divergence and convergence in treatment techniques. Of the psychoanalytic propositions mentioned above, the genetic is probably the most characteristic of psychoanalysis. The interplay between the genetic proposition and all of the other propositions provides one highly important orienting principle for the psychoanalyst in his endeavors to understand the complexities of the clinical data set before him; and the treatment techniques which he utilizes are designed to facilitate the study of maturational and developmental vicissitudes, i.e., genetic problems.

On the other hand, current interpersonal and intrapsychic dynamics are likely to receive the greatest emphasis in psychoanalytic psychotherapy, and there is less concern with the task of making detailed genetic reconstructions of the patient's past life. But many clinical conditions cannot be approached in such a simple, schematized fashion; both past and

present contribute etiological factors of importance. In some such instances, psychoanalysis might be attempted, but only with some technical modifications; and it might become difficult to decide whether the treatment is actually psychoanalysis or psychoanalytic psychotherapy.

Further, the contrast between the focus on the historic and the focus on the current loses its sharp outline in the treatment of the individual patient. Almost invariably, even the most present-oriented therapy must include some work with the patient's historical past and his psychological depths. Similarly, the most past- and depth-oriented therapy, of which "classical" or "orthodox" psychoanalysis is the model, must deal at times with the current extra-analytic life situation of the patient. And even psychoanalytic work with a specific patient (in its technical aspects which govern the actual treatment, as contrasted with a theoretic orientation of the analyst) generally deals explicitly with the past only after it can be demonstrated to the patient to be a current, living force in his relationship with the analyst and, to a lesser extent, in his relationship with others.

In this section, psychoanalysis and psychoanalytic psychotherapy will be considered separately; concurrently, further consideration will be given to the similarities and contrasts between them. Since theory and technique have been worked out in much greater detail for psychoanalysis than for psychoanalytic psychotherapy, psychoanalysis will be discussed first. That discussion will then be used as a foundation for a discussion of psychoanalytic psychotherapy.

Psychoanalysis: Historical Considerations

Use of hypnosis in treatment of hysteria. Psychoanalysis began with the treatment of neurotic patients by physicians engaged in general practice. Fraulein Anna O., a hysterical young woman who suffered from a multitude of visual and motor disturbances as well as disturbances of consciousness, was treated in 1881 by the Viennese internist, Josef Breuer. Breuer made the astonishing discovery that his patient's symptoms were effectively removed when she gave them verbal expression under hypnosis, a process which Anna O. described (in English) as the "talking cure" when she referred to it seriously, and as "chimney-sweeping" when she referred to it jokingly. In 1882, when his friend Breuer told him about his treatment of Anna O., Sigmund Freud was just completing his medical training. He was greatly impressed by Breuer's account, and 3 years later, in Paris, he described the case to the French neurologist, Charcot. Perhaps because he failed to capture Charcot's interest, Freud did not pursue the matter further at that time.

Subsequently, however, when he established a general medical practice in Vienna, he found that there were many hysterics among his patients. At first, he treated them by the various methods then in vogue, such as electrotherapy, hydrotherapy, and

rest cures. He was dissatisfied with his results, however, and, remembering Breuer's treatment of Anna O., he began to use hypnosis as a means of gaining access to his patients' otherwise unrememberable "reminiscences." Thus, the use of hypnosis for psychic catharsis was the *anlage* of psychoanalysis as a tool for the investigation of psychic processes of which the patient was not aware.

Repression and the need for discharge. Freud and Breuer continued to work together on the problems of hysteria and reported their findings in *Studies on Hysteria*, which was published in 1895. Reasoning from their clinical observations, Breuer and Freud explained hysteria as the result of traumatic experiences, usually sexual in nature, associated with a large quantity of affect which could not be dissipated in the usual ways, that is, either by "conscious reflexes" or by a gradual "wearing away." Instead, the affect was dammed up and barred from consciousness, only to return in a disguised form in the symptoms. And they summarized their observations in the formula, "*Hysterics suffer mainly from reminiscences.*" They assumed that for some reason or other, the memory itself was unacceptable to the patient's "ego"—a term used then much as "self" is used today—or that the traumatic experiences had taken place when the patient was in a dissociated state, which they called "hypnoid." For these reasons, the experience was suppressed and consequently in need of discharge through abreaction.

The need for discharge of dammed up affect was attributed to the "principle of constancy," which postulated that something in the nervous system, which they referred to in their writings as the "sum of excitation," is increased as a consequence of physical stimulation and that there exists a tendency to diminish that "something" to maintain the well-being of the organism. One of the primary functions of the psychic apparatus, they felt, was to keep the quantity of excitation as low as possible, or at least to keep it constant. Freud and Breuer thought of the excitation as a physical entity, a physiological stimulus which suffused the neurone and which required eventual discharge much in the manner of the reflex arc. They regarded it as somewhat analogous to an electrical charge, and the quantum of excitation, or energy, was called "cathexis."

Mind-body problem. Interestingly, Freud was strongly influenced by the Central European natural science tradition which centered around Helmholtz, and his initial interest in the field of medicine lay far from psychology. Rather, his training was in biology, which, at the time, included little of psychobiology. In fact, it was a field he abandoned only for practical considerations, on the advice of his professor of physiology, Ernst Brücke. In medicine, at first, he was interested primarily in the study of neurology, histology, pharmacology, and medicine; and he had written several monographs on those subjects by the time he was 29, including an essay on cocaine which ap-

peared in 1884. It was Freud's work in this area, in fact, that led to the study of the ophthalmologic use of cocaine.

Consequently, by the time *Studies on Hysteria* was published, Freud was confronted by a serious dilemma. The scientific disciplines of his day, medical and other, were unable to explain the puzzling phenomena of hysteria with which he was confronted in his medical practice. Freud, trained in the science of his day, continued to maintain that all psychological phenomena should be describable in anatomical and physiological terms. Yet he found that his clinical histories read more like stories, artistic productions which seemed to have little in common with scientific reports. Confronted by this discrepancy, Freud tried again and again to deal with body-mind problems. (The story of his early attempt at a solution of the problem is set forth in Ernst Kris's admirable introduction to *The Origins of Psychoanalysis*, a collection of letters and other materials which Freud sent to his friend Wilhelm Fliess, a prominent Berlin otolaryngologist.)

Breuer felt that the scientific data which were then available were not adequate to support Freud's physiological hypotheses, and he advised him to give up the attempt to reduce psychological events to physiological ones. In fact, Breuer was becoming somewhat resistant to the emerging discoveries of the importance of the role of sexuality in the causation of the neuroses, and he withdrew from his collaboration with Freud shortly thereafter. However, Freud persisted in his efforts to work out an acceptable theory of psychological events based on the concept that the psychic apparatus was a system of neurones and that all events in the neurone could be considered ultimately as quantitative changes. In 1895 Freud elaborated on this approach in a document entitled "A Project for a Scientific Psychology." Although he worked on the "Project" intensively over a 2-year period, Freud was dissatisfied with his final formulations. As a result, this truly amazing document was not published until 1954.

Evolution of psychoanalytic theory. In the 4 years immediately after his work on the "Project," Freud embarked on his first real psychoanalysis—that of himself. In addition, during these years he made major discoveries about *transference*, the importance of *infantile sexuality*, the *Oedipus complex*, and the traumatic potential of *fantasy*, as contrasted with actual external events. The Fliess correspondence contains the story of those discoveries. As his psychological understanding deepened, Freud began to realize that Breuer had been right about the inadequacy for his purposes of the science of the times, and he saw that a new set of working hypotheses was required. By 1899 he had reworked the basic principles of the "Project"; and he had created a genuine psychodynamics which, for the first time, seemed to have an independent validity, pending fuller under-

standing of the somatic aspects of the clinical phenomena.

The new psychological theories received their first full exposition in Chapter VII of Freud's *The Interpretation of Dreams*, which was completed and published late in 1899. Without question, the new hypotheses were much more useful than those Freud had formulated previously in dealing with the materials at hand—his patients' neuroses, dreams, in brief, the psychopathology of everyday life. Nevertheless, Freud himself never lost sight of their provisional nature. Thus, in his final publication, *An Outline of Psychoanalysis*, Freud wrote: "We know two kinds of things about what we call our psyche (or mental life): firstly, its bodily organ and scene of action, the brain (or nervous system) and, on the other hand, our acts of consciousness, which are immediate data and cannot be further explained by any sort of description. Everything that lies between is unknown to us, and the data do not include any direct relation between these two terminal points of our knowledge." Elsewhere in the *Outline*, he wrote: "The future may teach us to exercise a direct influence, by means of particular chemical substances, on the amounts of energy and their distribution in the mental apparatus. It may be that there are other still undreamt-of possibilities of therapy. But for the moment we have nothing better at our disposal than the technique of psycho-analysis. . . ."

Early psychoanalytic techniques. This brief historical survey of the early days of psychoanalysis provides an orientation for an understanding of the early therapeutic techniques and aims of the process. Psychoanalysis began with hypnosis; its goals were remembering and abreaction of unresolved traumatic situations; and its therapeutic effectiveness depended on suggestion. But patients seemed to fight the process; they were reluctant to give themselves up to the cure; resistances made their appearance. Furthermore, patients tended to embroil the physician in their neurotic conflicts. Transference phenomena were recognized as problems to be dealt with in clinical work.

As early as 1895, Freud had begun to give up the practice of placing his patients in hypnotic trance and instead was simply urging them to tell him all they could about themselves. This urging subsequently gave way to the present day technique of free association. More specifically, Freud instructed his patients to say whatever came into their minds, important or unimportant, related or unrelated, with a minimum of editing by the patient or direction by the physician.

The techniques of hypnosis, urging, and free association share in common the goal of bringing into consciousness something which is unconscious, something which is kept in the unconscious because it is unacceptable to the conscious self. The goal of treatment, as Freud wrote in the *Introductory Lectures*, was "making conscious what is unconscious, lifting

repressions, filling gaps in the memory—all these amount to the same thing." Hopefully, the patient, spurred on by his wish to get well and his wish to please his physician, would gain the courage to look at thoughts and feelings which he had had to keep outside his awareness previously. With the expansion of self-awareness, and at the expense of the repressed material in his unconscious, cure could be achieved.

Determinants of psychic functioning

Topographical model. The first model of a psychic apparatus which might be called truly psychoanalytic was the topographical model described in *The Interpretation of Dreams*. In that model, Freud assigned a role of limited importance to the function of consciousness, which had heretofore been regarded as the sum total of mental life by scientist and layman alike. The conscious was conceptualized as a sensory organ which scans the surface of the preconscious, directing attention (the technical term is "attention cathexis") first here, then there. The preconscious includes the thoughts and feelings which are easily available to consciousness through the process of "hypercathexis," i.e., the addition of small amounts of energy from the conscious to their own quanta of energy. Descriptively, the preconscious has the quality of unconsciousness; but Freud discerned an additional system of unconscious thoughts and feelings which are not as readily available to consciousness as are the contents of the preconscious and which, in fact, cannot be made conscious at all without overcoming strong resistances. He called that system the unconscious. It was the physician's ability to bring material in the unconscious to light which was crucial for the curative process.

The picture of psychic structure and of psychodynamic functioning presented at that time is too schematic and simple; nevertheless, it expressed major findings in a schema which is still highly valued. The whole apparatus, composed of the conscious, the preconscious, and the unconscious, was seen as operating with a force which merits the label of psychic energy, which, though not directly measurable, can be roughly quantified as increasing or decreasing.

Regulation of psychic energy. This psychic energy is regulated in two ways: the primary process holds sway in the unconscious; the secondary process is characteristic of the preconscious. In the unconscious, cathexis is freely mobile and displaceable. Leading to intensification of certain elements and reduction in the intensity of others; it is constantly pressing for discharge; and it operates without regard for time, space, or logic. By contrast, the energy of the preconscious is regulated more by temporal, spatial, and logical considerations. It is less imperious; and it gives rise to the modes of thinking which are most readily available to the waking, reasoning, and reflecting adult. Genetically, the primary process is

equivalent to the thought processes of the infant. Although it is gradually overlaid by the secondary process as the preconscious develops, the primary process persists as the mode of operation of the unconscious. It is the unconscious, with its mobile psychic energy, its nonverbal forms of thought formation, and its disregard for the external world, which gives to dreams, parapraxes, and symptoms alike their special and partly unrealistic qualities.

Thus, primary emphasis was placed on the unconscious drives and, in addition, on the moral judgments the patient might make about his impulses. The ensuing conflict with the unconscious drives was a central concept. One of the outcomes of this conflict was *repression*, which was regarded as pathological. The process of cure coincided with its removal.

Freud's evidence indicated strongly that psychic events are not random happenings, but have a discoverable cause, or perhaps several causes at the same time. Not only did Freud demonstrate the validity of this proposition in the treatment of neurotic patients, he also showed it to be equally true for the events of everyday life—dreams, humor, slips of the tongue and other parapraxes, even falling in love.

In short, psychoanalysis, then and later, has made essential contributions to the comprehensive understanding of human structure and function. Psychoanalytic findings have illuminated many of those areas of human life which formerly seemed murky and unclear. Even more important, in combination with the biological and the social sciences, psychoanalysis has begun to provide a reliable understanding of man, both in his internal and his external environments.

Outline of the history of psychoanalysis

First phase. The history of psychoanalysis may, for heuristic purposes, be divided into three phases. The first of these began with the publication of *The Interpretation of Dreams*, discussed briefly in the preceding paragraphs. (In addition, there was a pre-psychoanalytic period, formative in nature, which was discussed earlier in this section, during which *Studies on Hysteria* was published.) With *The Interpretation of Dreams* psychoanalysis proper may be said to have begun, for this work introduced the topographic model of the mind and the concept of a "depth psychology." This initial phase came to a close with Freud's publication of *The Ego and the Id* in 1923.

During this time, psychoanalysis, as *therapy*, was concerned with the removal of amnesias through the method of free association. Little attention was directed, at least at first, to those factors which we would now include under the rubric of ego psychology. As his clinical experience increased, however, Freud inevitably was forced to pay more attention to factors other than unconscious drives and the resulting con-

flicts. Thus, Freud's observations led him to postulate that, for various reasons, some patients are too narcissistic to be suitable subjects for psychoanalysis. They were unable to develop the workable transference toward the physician which is the hallmark of psychoanalytic treatment. Generally speaking, the narcissistic neuroses from which they suffer are the psychoses, in contrast to the transference neuroses, which include conversion hysteria, anxiety hysteria (the hysterical phobias), and the obsessive-compulsive neuroses.

The term "transference neurosis" has two meanings in psychoanalytic literature. It has a diagnostic and taxonomic meaning, in that it refers to various neuroses whose symptoms are formed somewhat along the lines of the process of dream formation. In the second sense, the term designates the principal event of a therapeutic psychoanalysis: the new neurosis directed toward the analyst, the unfolding and the resolution of which becomes the main analytic task. The transference neuroses in the first, or diagnostic sense, are also characterized by the tendency of patients of that group to form transference neuroses (this time, in the second sense) toward their analysts. (Both meanings of this term are discussed more fully below.)

However, melancholia seemed in some ways to be an exception. In his study of this syndrome Freud's attention focused once again on the matrix in which unconscious impulses were expressed, a matrix which was proving to be more complex than the prior division of the psychic apparatus into a conscious, preconscious, and unconscious. Repressing forces themselves, for instance, were found to be a part of the unconscious. A further revision in theory was called for, and the new hypotheses about the structure of the psychic apparatus were announced in *The Ego and the Id*.

Second phase: New structural hypothesis. With the emergence of the new structural approach, the technique of psychoanalysis took on new precision and focus. The ego was seen as a group of functions more or less accessible to consciousness. The most important function of the ego, perhaps, was to *mediate* between the demands of the id, the superego, and the environment. Anxiety was no longer to be regarded as a transmutation product of dammed up libido, as in the earlier ("toxicologic") theory. It could now be viewed as the ego's reaction to the threatened breakthrough of forbidden impulses. The previous duality of the drives, self-preservative and species-preservative, was found to provide, in part, a false dichotomy; and self-preservation was now regarded as an important ego function instead of an "instinct."

However, another dualistic concept, that of the *libido* and the *death instinct*, appeared at this time. The concept of a death instinct has not found general acceptance. But the aggressive drive, at first regarded as a derivative of the death instinct, has become a cornerstone of current psychoanalytic thought. Today,

aggression is thought of as coordinate with sex, undergoing comparable developmental sequences. Like sex, it may exist either in infantile, repressed forms, or in mature, integrated, constructive modes.

The effect of the new structural hypothesis on treatment was to open up a more extensive consideration of the total personality, not just those elements of the unconscious which were repressed. Almost immediately, the way was cleared for the study of character neuroses, in addition to symptom neuroses. In 1928 Wilhelm Reich showed that a person's "characterological armor" could be the object of analytic study; in fact, frequently, it must be analyzed as a preliminary to the uncovering of the traumata which are operative in neurosis. However, Freud had foreshadowed Reich's work in his paper, "Some Character Types Met with in Psycho-Analytic Work," which was published in 1916. Here he dealt with those patients who are wrecked by success, those who become criminals from a sense of guilt, and those who had experienced traumata for which they could not be held responsible (such as congenital deformities) and who consequently insisted that the world exempt them from the demands usually made on others (the "exceptions"). This is a good example of the way in which clinical observation preceded theory formation in Freud's work.

Third phase: Ego psychology. The third and present period, the period of ego psychology, began in 1936 with the publication of Anna Freud's *The Ego and the Mechanisms of Defense*. This was followed in 1939 by Heinz Hartmann's *Ego Psychology and the Problem of Adaptation*, in which the idea of conflict-free, constitutionally determined, adaptive ego mechanisms was proposed. More recently, Kohut and Seitz have suggested the mapping of the ego into an "area of progressive neutralization" which would include (in addition to Hartmann's conflict-free sphere) the residues of all benign nontraumatic learning, and an "area of transference," in which a barrier walls off more or less intensely repressed content from the neutralizing effects of the ego.

In fact, the contemporary psychoanalyst who thinks in terms of the therapeutic alliance works with patterns and traits which are part of the area of progressive neutralization, using them as a lever for the loosening up of the repression which contributes to the formation of symptoms and pathological character traits. However, the distinction made by Kohut and Seitz is *economic* as well as *structural*; that is, modes of energy regulation based on the dichotomy of primary and secondary thought processes provide the criteria for this newer mapping of the ego. The goal of therapy now may be formulated to a greater degree in terms of "neutralizing" the infantile, unconscious material, which may be either in the deeper layers of the ego or in the id. Abreaction alone, without neutralization and the resultant integration of previously repressed mental contents into the total

personality, is not therapeutic in the fullest sense of the word, although it may provide some temporary relief.

The more recent hypotheses about the structure of the psychic apparatus have clarified thinking about the treatment of syndromes previously considered inaccessible to analysis, particularly the psychoses. Further, an emphasis on the development of the ego and an understanding of its mechanisms and its relations to environmental figures have enormously facilitated the treatment of children by psychoanalysis. The psychoanalytic treatment of certain varieties of developmental lag, of delinquency, and of other problems which were not considered to be amenable to psychoanalysis previously is now attempted with increasing frequency. In theory and in clinical work, the structural hypotheses have not supplanted the older topographical considerations; rather they complement them.

Psychoanalysis: As Therapy

General considerations. The beautifully summarized, highly condensed clinical reports which appear in the psychoanalytic literature are likely to give a distorted picture of the analytic process as it goes along day by day, month by month, year by year. Descriptions of the work of years, when reduced to a few pages, give an impression of the clairvoyance of the analyst and of easy, dramatic insights. In reality, the process of clinical psychoanalysis is, for the most part, slow and tedious. The analyst, observing the principle of maintaining an optimal level of anxiety in his patient and the principle of optimal dosages of interpretation, tends to regard a sudden abreactive breakthrough as unfortunate and potentially traumatic. (Freud called it "an outright mishap.")

Therapeutic orientation. The historical sketch of psychoanalysis given above emphasized the necessity of undoing repression and of recovering lost memories. However, analytic work actually involves much more. The chief requirement is *the gradual integration of the previously repressed material into the total structure of the personality*. For, if the work proceeds too rapidly, there is the danger that the patient will experience analysis as a new trauma.

The work of analysis, then, is much concerned with preparing the patient to deal with the material which has been uncovered, to provide a kind of progressive desensitization to noxious psychic material, dealing at first with remote derivatives of crucial traumatic conflicts, and later with the conflicts in their more primary forms. At times, this preparation takes the form of instruction, which focuses, in particular, on training the patient to be sensitive to his inner promptings, that is, in the method of introspection which is the principal tool of psychoanalysis. At other times, work proceeds on uncovering hidden resistances to the analytic process, and at still other times, the work involves dealing with the noxious

psychic materials directly. Patient and analyst seldom follow a straight path to insight. Instead, the process of analysis is more like putting together, a few at a time, the pieces of an immense and enormously complicated jigsaw puzzle.

Approximate duration of treatment. One of the prerequisites for competence in the practice of analysis, as Kohut and Seitz have pointed out, is the capacity to tolerate ambiguity, to resist false and premature closure on psychological matters, to proceed on the assumption that there is always likely to be still another meaning of a psychic event which has not yet come to light and which may be important. Psychoanalysis is a process which takes time, and one condition of the analytic setting is that both patient and analyst be prepared to make a commitment to the process for an indefinite period. The argument that a lifetime of difficulty cannot be straightened out in a few months is a valid one. Concomitantly, however, as is true of all growth processes which should not be rushed, there is a welcome acceptance of increasing strength and of an end point of resolution and independence and of the resolution of difficulties.

The number of analytic interviews included as part of the preparatory, or "training," analyses required for future psychoanalysts range from less than 200 sessions at one end of a continuum, to almost 2,000 sessions at the other end. (Many psychoanalytic institutes now require a minimum of 300 hours for a preparatory analysis.) On the average, most analyses, whether conducted for therapeutic reasons, or as part of the training of future psychoanalysts, require between 2 and 5 years. The American Psychoanalytic Association recommends at least four analytic sessions each week, exclusive of time out for vacations, etc., both for preparatory analyses and analyses conducted by candidates at psychoanalytic training institutes. This figure reflects a tendency toward less frequent interviews, in comparison to the early days of analysis, when patients were seen daily except Sundays. On the other hand, however, most analysts feel that, on the whole, analyses are longer in duration.

The reasons for the tendency toward longer analyses vary, and they reflect both a change in the kind of problems patients are bringing to analysis, and an increasing stringency on the part of analysts with regard to the criteria for termination of treatment. In all likelihood, many of the short analyses which abounded in the formative years of psychoanalysis would not be regarded as successful analyses today; rather, they would be evaluated as cures which were based on the effects of suggestion (which was left unanalyzed), i.e., so-called "transference cures." Despite the fact that, on occasion, treatment may produce long lasting improvement and may be satisfactory from the patient's viewpoint, such cures are not analytic in the strict sense that a neurotogenic conflict has had a far reaching resolution.

Analytic setting. In addition to the duration of

treatment and the frequency of interviews, another characteristic of the analytic setting is the supine position of the patient on the couch or sofa, with the analyst seated behind the patient, partially or totally invisible to him. The use of the couch is, of course, a convention which had its origin in Freud's early experimentation with hypnosis. However, even after he had stopped using hypnotic techniques, Freud continued to find the couch a useful device. For one, it meant that the patient did not have to look at him, which he found uncomfortable when it continued for many hours. But beyond such considerations, the use of the couch was found to have a specific dynamic significance which transcended its original value: it assists the analyst in his attempts to produce the controlled regression which favors the emergence of repressed material. More specifically, the reclining position of the patient in the presence of the analyst will in most instances reproduce an ancient parent-child situation symbolically, although the specific nuances of its meaning will vary from patient to patient. Freed of the necessity to interact constantly with the analyst on the level of a real, adult, face-to-face and day-to-day relationship, the patient finds himself focusing more on his own inner thoughts, feelings, and fantasies, which can then become the content of his free associations.

Role of the analyst. An important factor bearing on the effectiveness of the analytic process is the analyst's attitudes, conscious and unconscious, toward the conflicts of his patient. Ideally, the analyst, who is himself well analyzed, is able to maintain an attitude of benevolent objectivity toward all the facets of his patient's behavior. In fact, however, just as the patient may form transferences toward the analyst, the analyst may form counter-transferences toward his patient if his therapeutic efforts are hampered by residuals, or portions, of old conflicts. And, like the patient's transferences, the analyst's *counter-transferences* are illogical and involve a repetition of the past in the present, or the inappropriate use of a stereotype. Moreover, since they produce a distortion in the analyst's perceptions of his patient, they impede the progress of analytic work. If, for example, the analyst has some need to ward off the same impulses with which his patient is struggling, impulses which are being intensified by the analytic work itself, a situation is set up which is characterized by a resistance of both patient and analyst to dealing with repressed material. The analyst's preparatory analysis is a safeguard, but it is by no means an iron-clad guarantee against such a problem. To avoid this problem requires diligent self-scrutiny by the analyst, as part of his never ending efforts to increase his self-understanding.

Psychoanalysis: Treatment Method

Overview. The chief external elements of the analytic situation have been mentioned. In addition, the

patient should be strongly committed to a persistent and stringent attempt at *self-understanding*. His life situation should be favorable enough to permit him to come for his analytic sessions regularly, and for as long as might be necessary to achieve his and the analyst's goals. He must agree to persist in the attempt to use the method of free association, which will be discussed in detail later.

But an analyst, a suffering patient, and compliance with the superficial requirements of the analytic setting do not necessarily make an analysis. The patient—and his analyst—must be able to participate in the analytic process, which consists primarily of the patient's recognition in himself (with the help of his analyst) of progressively deeper conflicts and the useful integration of warded off drives into his ego.

It seems likely that the ability to utilize the analytic process for curative purposes may vary from one type of neurosis to another. For instance, an obsessive-compulsive patient might come to analysis prepared to talk unceasingly and to examine the contents of his mind intellectually, but determined to keep his feelings at a safe distance. One of the defensive patterns basic to the development of obsessions is, in fact, the same separation of idea and feeling which the patient might show in his approach to analysis. On the other hand, an hysterical patient, swept along as he is by intense feelings, might very well have more difficulty adhering to the formal requirements of the analytic situation; yet, at the same time, he might be able to make rapid strides in the direction of integration and cure.

The "fundamental rule." The analyst and his patient share a division of labor. The analyst's job is to listen to his patient, to try to understand, and, choosing the moment, to interpret what his patient reveals to him. The patient's job, on the other hand, is indicated in the "fundamental rule." As part of the realistic collaborative approach to the cure of his neurosis, *the patient agrees to be completely candid with his analyst*. But analytic candor requires that the patient reveal things about himself which he does not even know that he knows. A statement representative of Freud's instructions about this aspect of psychoanalytic technique appears in *An Outline of Psychoanalysis*:

We pledge him to obey the fundamental rule of analysis, which is henceforward to govern his behavior towards us. He is to tell us not only what he can say intentionally and willingly, what will give him relief like a confession, but everything else as well that his self-observation yields him, everything that comes into his head, even if it is *disagreeable* for him to say it, even if it seems to him *unimportant* or actually *nonsensical*.

Implicit in the fundamental rule of psychoanalysis are two interrelated principles. First, in psychoanalysis there is a clear emphasis on the value of recognition and verbalization of psychic contents, of ideas, impulses, conflicts, and emotions. Second, psychoana-

lytic technique emphasizes the principle that action based on impulse without adequate prior consideration is to be avoided. In fact, the supine and relatively immobile attitude of the patient on the couch favors verbalization instead of action; this condition is further emphasized by the analyst's accepting attitude toward his patient's verbal productions. Prohibition of action bars musculoskeletal channels for the discharge of drive tension, which is then redirected into psychological pathways where, depending on the state of resistance, it may eventually reach verbal levels. This state of affairs swings the balance toward conscious remembering and away from blind repetition outside of awareness—or "acting out," as it is called. (In psychosomatic disorders, drive tensions may also be discharged through visceral channels, introducing additional problems in treatment.)

Some patients may take the fundamental rule so literally that they sabotage their treatment while giving an appearance of meticulously complying with its requirements: they may parody its spirit while obeying its letter. This is particularly likely to occur in some obsessional states, where the fundamental rule may be used as a weapon against the analyst, rather than the neurosis. Some analysts, therefore, do not always give their patients explicit statements about the fundamental rule, preferring instead to lead them to discover it for themselves through a study of the obstacles which they place in the way of communication. Properly observed, however, the fundamental rule leads to the patient's use of the technique of free association.

Free association. This is actually a misnomer, since the associations are soon seen to be directed by three kinds of unconscious forces: (1) the pathogenic conflicts of the neurosis, (2) the wish to get well, and (3) the wish to please the analyst. The interplay between these factors becomes very complex and at times threatens the progress of the analysis, as, for example, when some impulse which is unacceptable to the patient and which is a part of his neurosis comes into conflict with his wish to please his analyst, who he assumes also finds the impulse unacceptable. Or, the wish for cure may imprint a stamp of unreality upon the analysis at its inception, since the patient may see the analyst as a replica of some powerful, benevolent figure out of his real or fantasied past. There is an archaic quality about such intensely positive feelings and an archaic quality about the illogical negative feelings with which the analyst becomes invested. It may be difficult to demonstrate to the patient the illogical nature of his positive feelings, since he desperately wants an omnipotent and omniscient ally against the inroads of neurosis. Similarly, it may be difficult to demonstrate to the patient the illogical nature of his negative feelings, since he may be convinced that offense is the best defense. (These are merely generalities based on broad scope reference to positive and

negative feelings, which in actual clinical work must be specified, along with their specific consequences.)

Not even the wish to get well can be taken for granted, since it may be overridden by a stronger urge to suffer. Some patients seem to feel that they do not deserve to be well and meet each therapeutic advance with a fresh wave of illness, introducing additional problems in treatment.

The "rule of abstinence." The second principle involved here is another "rule," the "rule of abstinence." This does not mean, as it is often interpreted, that a patient must forego sexual gratification or give up his favorite foods. Instead, it is only through the optimal frustration of the patient's wishes in the framework of the analysis that the analytic process is propelled forward, that the patient becomes conscious of his psychic tensions, instead of reducing them in unproductive gratification or keeping them in repression. The key phrase, perhaps, is "optimal frustration," since few patients could tolerate for long a totally sterile, nongiving analytic environment; yet the analyst's temptation to play the role of the indulgent parent and to give beyond the requirements of the analytic process must be strongly resisted if the work of analysis is to proceed. Frustration in the analytic situation, which is so essential to forward motion, must, like interpretation, be optimally timed and dosed according to the patient's capacity to work effectively at any given time.

Transference. One criterion by which psychoanalysis can be differentiated in principle from other forms of psychotherapy, including psychoanalytic psychotherapy, is the management of transference. The term "transference" has been used earlier in this section in several contexts, without pausing for definition. Since it is central to this discussion and has gained wide currency in contemporary psychiatry as well, it would be productive to specify the sense in which it is used in classical psychoanalysis, as opposed to its broader implications in general psychiatry.

In general psychiatry, the term "transference" has come to be used as a loose designation for all aspects of the patient's feelings and behavior toward the physician. This includes rational and adaptive (overt) aspects, as well as those irrational distortions which arise from unconscious strivings. Therefore, when it is used in this encompassing sense, it might be more appropriate to refer to transference as a "relationship." In contrast, in psychoanalysis, transference is conceived of as an endopsychic phenomenon, that is, as a phenomenon which occurs entirely within the mind.

Definition. In *The Interpretation of Dreams*, Freud wrote that in the preconscious there are purposive ideas, ultimately derived from unconscious sources, which are "always on the alert." Using an anthropomorphic phrase to dramatize the concept, it can be said that these wishes may seize control of a neglected

train of thought in the preconscious which might itself be without any great significance. "They may establish a connection between it and an unconscious wish, and they may 'transfer' to it the energy belonging to the unconscious wish. Thenceforward the neglected or suppressed train of thought is in a position to persist, though the reinforcement it has received gives it no right of entry into consciousness. We may express this by saying that what has hitherto been a preconscious train of thought has now been 'drawn into the unconscious.'" The distortions of the otherwise rational manifest content of the dream are a clear example of the taking over of the preconscious material by unconscious wishes; for that reason, dreams, as well as parapraxes, are thought of as "transference phenomena." Freud saw too that the mechanisms of symptom formation show great similarity to those of dream formation.

Transference as distorted unconscious wishes.

Very early in his work, Freud observed also that patients tend to distort their view of their analyst in essentially the same fashion that they distort reality material in the dream. The patient's view of his analyst, like the dream pattern mentioned above, is modified by unconscious wishes which are always on the alert to attach themselves to a person in the environment. Since these repressed wishes arise from infantile sources, the relationship with the analyst is strongly influenced by the patient's struggle to gratify his unconscious infantile wishes through the analyst.

Such transference distortions are not limited to the psychoanalytic setting but arise in all conditions of human life. This includes a patient's relationship with any physician, where the reality of being a patient, with some degree of helplessness, combined with the realistic, appropriate expectation of receiving help from the physician, serves to reawaken the old parent-child wishes and struggles. But for several reasons, a neurotic person is more vulnerable to transference distortions of all of his relationships than is the person "free" of neurosis.

The interpersonal sense in which the term "transference" is described here, that is, in the sense of the illogical and emotionally colored distortions of a relationship with another person, is a variation of the endopsychic pattern previously mentioned. This becomes most readily apparent in the analytic situation, where the analyst attempts to conduct himself so that he becomes available for use by the patient much in the fashion of a bit of "day residue"—one of those insignificant bits of preconscious thought chains which gain importance through the transference of intense infantile wishes. This is in contrast to nonanalytic relationships, in which the relative freedom of both of the participants to respond more openly to each other may obscure the essential transference nature of some of the reactions; for example, marital partners might have strong, but unrecognized, transference reactions to each other.

Transference as generalized character pattern.

In a somewhat broadened sense, "transference" includes not only those distortions in relation to the analyst which derive directly from transferred infantile wishes, but also the distortions which derive from other intermediate dynamic sequences in which characterological defenses against those wishes predominate. One patient's over-all suspiciousness toward his analyst or another patient's blind trustfulness may be included under the rubric of "transference," whether it is a transference in the pure sense or part of a generalized character pattern which became evident during or after the latency period, without either distortion having been directed previously toward one of the crucial figures of childhood.

Nature of transference phenomena. A central characteristic of transference phenomena is their repetition. In those instances when transference occurs in the strict sense of the term, the unconscious wishes which are transferred are from the past. Hence, their intrusion into the present involves a reliving, and it is this factor which gives such a transference its unique capacity to reproduce the past before the eyes of the analyst in the present. Similarly, in those instances of transference which represent the fitting of the analyst into a characterological scheme, the understanding of the distortion also leads deeply into the past. This is especially evident in the form of repetitive patterns or stereotypes of behavior in the analysis.

One is tempted to conclude from this account that definite and specific events are frequently repeated or relived in the transference. In fact, this kind of repetition occurs only rarely. Rather, most of the analytic work is concerned with repetitive patterns of behavior which can be recognized as anachronistic, as somehow inappropriate to the present. Moreover, those patterns or stereotypes have many different, sometimes almost incompatible, meanings; and they call for some degree of reinterpretation, according to the context in which they arise.

Course of analysis. It is customary to think of an analysis as comprised of three principal phases—an opening, a middle, and a termination phase—which Freud likened to the opening, middle, and end games of chess. Each of these phases—in chess and analysis alike—has its special characteristics and techniques.

Initial phase of analysis: Orientation. From the analyst's point of view, two matters are uppermost during the initial phase. First, there are diagnostic questions to be asked and answered. This involves much more than attaching a label to the patient. Rather, during this opening phase, the analyst tries to get a sense of the plot, or story, of his patient's life, to get a picture of the major conflicts with which he was confronted in the course of his development, together with their attempted solutions. In this, the analyst is aided by the patient's agreement, under the terms of the fundamental rule, to tell him as

much about himself as he can, which usually includes a great deal of his past history.

The analyst's second concern is the establishment of a good collaborative working relationship with his patient. The opening phase is marked by evanescent transferences and a mutual "sizing up," as well as a progressive commitment to the analytic process. It involves, among other things, the process of training the patient to be a patient, referred to earlier. In this phase, the patient usually gets some relief from his symptoms simply from talking about himself in a supportive, accepting analytic climate.

Second phase of analysis: Transference neurosis. Sooner or later, though, the patient becomes more preoccupied with the present than with the past, and particularly with the analysis itself. This phenomenon occurs at the beginning of the second phase, which can be identified as the transference neurosis. In contrast to the transient transference reactions of the first phase, the transference neurosis is a somewhat variable but sustained network of transferences, in which the patient reproduces much of the essential material from his past. This new neurotic formation, a kind of refocused set of patterns which are now directed toward the analyst, arises in part as response to the analytic setting itself, with its use of the couch, of free association, and its symbolic reproduction of the parent-child relationship. It arises in part, too, from the effects of the analyst's interpretive activity, which may tend to limit the channels for the expression of unconscious strivings. In addition, the presence of the analyst rekindles the hope of achieving some of the impossible goals of childhood, and therefore some of the crucial interpersonal responses of childhood.

Although the transference neurosis was originally regarded as a serious obstacle to analytic work, analysts soon realized that in the repetitions which are manifested in the transference neurosis the analyst could observe first-hand many of the important conflicts and conflict-solutions of his patient's childhood, conflicts which had undergone repression long since, but which had not been otherwise resolved. Consequently, the transference neurosis, i.e., its gradual unfolding and its eventual resolution, becomes the central concern of the analysis.

The repetitions in the transference neurosis differ in some significant respects from the prototypal experiences which they seem to reproduce. At the time the traumatic events or situations which became the core of the later neurosis occur, the child's ego is relatively helpless against the demands of the id; and reliable, reality-adaptive ways of handling primitive id drives are not yet fully developed. In addition, for the child, the environment itself actually is, or at least seems to be, a greater source of potential danger than it is for the mature adult. In the analytic situation, however, under the conditions of the therapeutic alliance, the patient's besieged ego finds a new and strong ally in the analyst; and his superego's exces-

sive demands are made less powerful because of the patient's identification with the analyst.

But the situation does not remain simple and unclouded for long. Since the undoing of pathological repression is the hub of analytic work, the analyst, by insisting on a recognition of unwanted impulses, may seem to be siding with those impulses which are in repression. Sooner or later the patient will feel impelled to repeat old ego or superego defenses against threatening impulses, but now these defenses are also directed against the analyst, who stands for such impulses. In the simplest situation, an infantile sexual impulse which is now directed toward the analyst becomes the occasion for a variety of equally infantile guilt feelings. At times, the hope of finally gratifying ungratifiable infantile strivings overrides all other concerns, including analytic progress. In either event, motives have arisen for resisting the progress of the analysis.

Much more complex transference situations may evolve, as well, as indicated in the following example reported by Anna Freud in *The Ego and the Mechanisms of Defense*.

One of Miss Freud's patients had violent outbursts of aggression toward her analyst and others. During these episodes the patient felt that these people were keeping secrets from her, and she felt deeply disappointed and critical. In her analysis it was observed that the outbursts of aggression coincided with the threatened emergence of hidden masturbation fantasies for which she expected to be criticized. The forbidden fantasies were kept in repression; that is, they were the patient's secret, which she hid even from herself. The patient identified thoroughly with the anticipated criticisms, and attempted to solve her conflict by attributing her secret fantasies to others, including her analyst, and then redirect her criticism toward the analyst.

By the time the analysis is well into the phase of the transference neurosis, however, the analyst and patient will have firmly established a base line of collaboration and trust, so that their relationship can tolerate the stresses and strains imposed upon it by illogical strivings, both positive and negative. The crucial issue here is whether the patient is beginning to develop his power of self-observation in the analysis, so that he is able to stand beside himself, so to speak, and to evaluate objectively his own emotional experiences—at first through the eyes of his analyst, and later through his own. The specific fate of the previously ward off impulses is immaterial; they may be integrated into the ego in less infantile forms, or they may be repudiated with some finality. Either way, they no longer are active as foci for neurotic conflicts.

Termination of treatment: Resolution of transferences and infantile conflicts. The termination phase begins when the patient has finally relived much of the primary infantile situation and has begun to resolve infantile conflicts in various ways. Old conflicts are successfully reworked, with different, more adaptive results. In the hypothetical ideal analysis, the work of synthesis—of going ahead from the new

beginnings made possible by the analysis of the transference neurosis—is primarily up to the patient. The goals of the analysis have been reached if the patient becomes free enough to develop in his own way, although that development may not be fully apparent until long after the analysis has been formally terminated.

An important task of the termination phase is the dissolution of those positive but illogical bonds which at first served to propel the analysis forward. If there is not a thorough confrontation with reality at this stage of the analysis, it is possible that the analysis will fail. In fact, unresolved transference, both of negative and positive feelings, may necessitate reanalysis by the same or by another analyst. After the illogical, infantile components of the relationship have been removed, the analyst may still remain as a real figure to his patient. But it is the final dissolution of the transference bonds between patient and analyst which, in the long run, differentiates analysis from cure by suggestion.

As mentioned above, the events which have been described here are characteristic of a somewhat hypothetical ideal analysis; in daily practice they do not always proceed in the order given. Some patients, for example, start analysis with a full blown transference neurosis which has developed in advance of the initial interview and which may have taken shape under the stimulus of the expectation of being analyzed—whatever dynamic meaning that may have for the particular patient. Another patient may never experience a classical transference neurosis during his analysis but may, perhaps, experience it in some form after the termination of analysis. Or the transference neurosis may be so dim that it rarely comes into clear view. "Normal" physicians who undertake a preparatory analysis as a part of their analytic training, in particular, may demonstrate the transference neurosis in attenuated form during treatment. Frequently, however, after the period of analytic training is over, those same physicians will experience a classical transference neurosis during a second analysis, suggesting that its earlier development may have been inhibited by the demands of the training situation.

Interpretive process. In the hypothetical classical analysis, the intervention of the analyst in the neurotic conflicts of his patient is virtually limited to the process of interpretation. Classical analysis makes no provision for such measures as role-playing or manipulation of schedules; and the requirement that the analyst conduct himself so that he is available for use by the patient as a bit of "day residue" restricts his reality dealings with his patient to the bare essentials of arranging practical matters such as appointment times, necessary schedule changes, vacations, or fees.

Because of its importance, it is appropriate to examine the process of interpretation in some detail.

The verb "to analyze" means, in this context, simply to lay bare conflicts, portions of which have been unconscious. In a sense, this is a statement of the technical goals of the analysis as a whole, as well as a description of the minute-to-minute course of a single analytic hour. "To interpret" means to make intelligible and meaningful to the patient those psychological events which he has not hitherto understood. It means to place a seemingly meaningless psychological event into a chain of events where it seems to "fit," to belong, to become understandable.

The function of interpretation in relation to the transference. As mentioned earlier, foremost among those factors which are considered conducive to the development of a therapeutic regression is the analytic situation itself. This alone, in the view of some analysts, is probably sufficient to initiate the transference neurosis. In addition, however, there is general consensus that the interpretive therapeutic activity of the analyst facilitates the therapeutic regression.

Discussion of one of the important distinctions between the interpretive process in psychoanalytic psychotherapy and in psychoanalysis proper is relevant in this connection. In analytic psychotherapy, the patient's attention is directed toward extratherapeutic situations and events to a greater extent than is characteristic of psychoanalysis. In contrast, in psychoanalysis the analyst directs the patient's attention primarily to the events within the analysis itself, and to intrapsychic events. To epitomize this contrast (once again, in oversimplified form), activity in psychoanalytic psychotherapy may be described as centrifugal, that is, it leads away from the patient-therapist axis. But in analysis proper, the analyst's interpretations are centripetal, i.e., toward the patient-therapist axis. Thus, in psychoanalytic psychotherapy, interpretations focus on the transference only in its general interpersonal sense; however, in psychoanalysis proper, the transference constitutes the principal frame of reference for interpretation.

Concomitant with the centripetal direction of interpretation in a psychoanalysis—and, in fact, a necessary part of the interpretations—is the relatively greater attention paid to material which provides access to the deeper layers of the ego and to the id. This includes the interpretation of dreams and the analysis of fantasies and parapraxes, particularly when they seem to involve the analysis and the analyst.

Dream interpretation. The paradigm of psychoanalytic interpretation is the interpretation of the dream. Freud demonstrated that, contrary to the prevailing scientific opinion before 1900, dreams are meaningful and can be set into a context of happenings where their nonsensical elements become sensible ones. A full exploration of the meaning of a dream required the investigation of both current and past trends which are combined into a unity in the dream's manifest content.

More specifically, the technique of dream interpre-

tation must be considered from several viewpoints in planning the strategy of treatment. A dream is, of course, a sort of commentary on the events of the preceding day which arises from the deeper (i.e., unconscious) layers of the ego. The unconscious portions of the ego include events from the more distant past as well. Thus, the study of current distortions, as they are revealed by the mechanisms involved in the formation of the dream, provides valuable clues to the specific nature of those aspects of the past which are being relived by the patient in his relationship with the analyst. For obvious reasons, dream interpretation, however, can easily become a game played by patient and analyst, in which aspects of the dream are "interpreted" in much the same way a person looks up the meaning of a word in a dictionary. For that reason, dream interpretation must be used cautiously in an analysis, lest it become, as may anything else, a means of obstructing the unfolding of the transference neurosis. Nevertheless, long stretches of an analysis might be characterized by little except dream analysis: the other events of the transference might be so obscure that the patient's dreams may provide the only reliable index of what is going on. One of the principal stimuli to dream formation is the analytic climate itself, and under any circumstances the analysis of dreams provides indispensable information about the transference relationship which cannot be obtained in any other way. At the same time, dream analysis serves to intensify the transference relationship.

Interpretation of current conflicts in historical perspective. Theoretically and ideally, a complete psychoanalytic interpretation will include meaningful statements of current conflicts and of the historical factors which influence them. Such an interpretation would contain formulations of both sides of current and past conflicts, the defensive maneuvers which are used to lessen the impact of the conflicts, and the reasons why the conflicts are active currently. However, complete interpretations of this kind are seldom made to the patient in the course of an analysis; and when they are, they are most often used as a summarization of a long period of analytic work. Most of the comments which are actually made to the patient are much more limited in scope and deal with matters which are of immediate concern.

Detailed and elaborate interpretations are seldom arrived at in one piece; rather, they take shape gradually as the analytic work goes along. The piecemeal interpretive work must be concerned now with one side of a conflict, now with the other, or again with new conflicts which come into existence as inappropriate solutions to prior conflicts are attempted. Often, the simple repetition of a word, properly timed, can function as an interpretation by calling the patient's attention to a bit of "hidden" material. Conversely, an elaborate speech by the analyst may reveal nothing new or may actually impede forward motion of the

analysis. But occasionally—and particularly under the circumstances noted above—a full discussion (and synthesis) may be helpful.

The timing of interpretations. It is more difficult to formulate clearly what constitutes proper timing, and often this boils down to the analyst's tact and his empathic understanding of his patient. One danger is the too deep interpretation. Another is an interpretation which is made prematurely or which simply misses the point because the patient is not concerned with the subject matter at the time. To guard against this, it has been suggested that the analyst interpret something just before the patient might see it anyway, to interpret material charged with feeling, or to interpret "at the level of the focal conflict."

Of these various approaches to timing, French's notion of the focal conflict seems to give the analyst more cognitive control of the interpretive process than do the others, which rely, by and large, on what is called "intuition." French maintains that the patient is usually occupied with only one conflict at a time; this is the matter with which he is immediately concerned and which is surrounded by the greatest potential affect. Such a conflict, then, is "in focus." In good part, the analyst arrives at his own diagnosis of the conflict intuitively, but French's method provides cognitive means for checking the formulation.

In the first place, all of the material of a given hour—dreams, associations, nonverbal acts—must have some psychologically rational relationship to the conflict. If large portions of the material cannot be seen in meaningful relation to the postulated conflict, then some other conflict probably is in focus. In the testing and acceptance or rejection of hypotheses, the analyst may be guided by the annoying discrepancies which are incompatible with his formulation; and he should be ready to discard his hypothesis in favor of another which can accommodate these discrepancies. A second major consideration is that of a "fit" between the conflict which is focal and the material which preceded it in earlier hours—the very important principle of continuity. If the analyst suddenly finds that each hour seems to stand by itself and cannot be related to those which preceded and followed it, then he is probably not understanding his patient correctly. Again, the inability to formulate a focal conflict for several hours in succession is usually a signal that something important has been overlooked.

Strategy. Regarding the strategy of analytic interpretation, little has been said. Assuming that the analyst knows what is in focus, he must still assess the patient's capacity at the moment to benefit from interpretive intervention. The patient's lack of preparedness to deal with a direct interpretation may lead to the analyst's decision to bide his time while he tends to other factors, such as the reduction of anxiety through support.

It should also be pointed out that in French's for-

mulations of focal conflict theory, conflicts which are in focus initially may be far removed from the nuclear genetic conflict of the neurosis. In the analytic setting, however, the consistent application of focal conflict interpretation will cause the nuclear conflict eventually to become focal and subject to interpretation.

Psychoanalysis: Dynamics of Cure

The way in which an analytic cure comes about has not been fully formulated, but on some points there is more or less general agreement.

1. Although the process of analysis depends on the effects of suggestion at some stages, these effects must in the long run be removed. Otherwise, the cure may be dependent on the continued influence of the analyst.

2. The process of cure in analysis involves the undoing of repression safely and effectively, and both the repressing forces and the repressed strivings must be accounted for. Various formulations about the repressing forces have appeared in the literature, and several analysts have suggested that repressing forces are diminished when the patient substitutes the analyst's superego for his own. In effect, this would weaken the repressing forces as long as the patient remains in analysis. However, if the cure is to be a lasting one, it would be necessary for the patient's superego to undergo a permanent modification.

In neurosis, the superego is usually excessively strict; nevertheless, it is often corruptible and unreliable, and it cannot be depended on to contain within bounds the primitive strivings toward which it is directed. Permanent modifications of the superego come both from an identification with the more reliable and more benign superego of the analyst and from repeated confrontations with reality. Again, changes in superego functioning are a logical result of changes in ego functioning: conditions for the adult are no longer what they were for the child. The ego of the adult has less to fear from the repressed impulses themselves: it is finally in a position either to accept these impulses or to renounce them.

3. Frequently, toward the end of an analysis, a patient will recall some very positive memories about the parent figure he has consistently maligned. Occasionally, the analyst may be taken by surprise when these memories actually appear, although he may have inferred their existence previously from various leads. And the patient may be even more surprised, since he had been so convinced of the bad or evil qualities of the parent.

This unexpected appearance of memories of affection and understanding suggests that another factor might be at work in the dynamics of analytic treatment. It seems possible that in erecting defensive processes to repress the memory of some of the experiences of childhood, the ego shrinks away not only from negative memories, but also from positive

memories. Analysis, then, might have as one of its effects the emancipation from repression of certain nontraumatic memories as well as traumatic ones. Further, such a process may be significant in the development of greater strengths in ego functioning. The memory of a parent's love, and of loving a parent, may become a nodal point of strength. In general, the revival of memories of positive childhood experiences takes its place beside the identification with an essentially benign but realistically perceived analyst as two of the experiences which are indigenous to the analytic process through which the ego is strengthened.

4. The impulses themselves undergo change. Once freed from repression, it becomes possible for their infantile forms, characterized by the primary process, to undergo modification. More specifically, they enter the area of progressive neutralization of the ego where they can undergo gradual "taming." Analysis offers the possibility of an actual reduction in the intensity of the components of the conflicts, as well as the possibility of finding more acceptable ways of handling impulses of unreduced intensity. A successful bit of analysis is frequently followed by the patient's wondering what all of his concern and anxiety had been about in the first place. This is not because some new defense mechanism, such as denial, has come into operation, but results from the taming of the impulses themselves and their integration into the ego. In that way, instead of the new solution being largely a more acceptable method of channeling unmodified infantile strivings, the primary process quality of the drives themselves is lessened, and they take on a more reality-adaptive form instead. Some analysts have hypothesized that, at first, the drives pass through the "soothing" ego of the analyst. In any event, the goal of analysis with respect to the drives is to transfer them from the area of transference to the area of progressive neutralization.

Psychoanalysis: Indications

From considerations such as these, it follows that the primary indication for analysis is the diagnostic finding that, in all probability, the patient has had long standing conflicts which continue into the present in an active but unconscious form and which produce signs or symptoms, or character problems, sufficient to justify extensive treatment. The analytic patient has a conflict not with his environment (although it may manifest itself as such) but within the structure of his own personality. That conflict is inaccessible to consciousness, and the frustrated drives which are part of the conflict repetitively press for discharge or expression. With this phrasing of the internal dynamic situation of the patient, it becomes clear that the analyst can become available as a transference target for the patient's unconscious strivings. The ensuing transference reactions are vital elements in analytic treatment.

The "ideal" patient population. The concept of

the primacy of past conflicts with still unresolved strivings which are capable of being transferred to the analyst led to the identification of a group of clinical entities in which such responses could be expected to occur. More specifically, as mentioned earlier, psychoanalysis was considered by Freud to be the ideal treatment for the hysterics (conversion reactions, and the hysterical phobias or anxiety hysteria) and the compulsion neuroses. Analysis has also been considered the best treatment for certain perversions.

In recent years, however, analysts have noted that, at least in urban populations, patients with hysteric and compulsion neuroses seem to present themselves for treatment somewhat less frequently than they did in the past. They have been replaced by those with analogous character neuroses, that is, with a variety of oral, anal, phallic, hysterical, compulsive, and other character disorders. The psychoanalytic treatment of such character disorders has become commonplace, based in part on the development of ego psychology stimulated by Freud's structural formulation, by the pioneer investigations of Wilhelm Reich and others in the study of the process of character analysis, and by the psychoanalytic study of children.

Extensive clinical experience has indicated, however, that clinical diagnosis which is based on "standard" criteria is, in itself, only an incomplete guide to a decision about indications and contraindications for analysis. The clinical diagnosis must not be too simple; it must be thoroughgoing and sophisticated. And the individual patterns within the diagnostic group must be considered thoroughly. For example, an hysteric suffering from a monosymptomatic conversion may be defending himself against an underlying psychosis which could be aggravated seriously by analysis. Also, in less obvious ways, a severe obsessive-compulsive neurotic may be paranoid. One phobic patient may be analyzable; another may not be. Individualized study of the patient's conflicts is essential. In addition, attention has been focused recently on the study of the ego itself as a guide to analyzability.

Patient's motivation. Of the essence in assessing analyzability is the estimate of the patient's ability to form an analytic pact and to maintain a commitment to a progressively deepening analytic process which attempts to bring about internal change through increasing self-awareness. The ego of a patient in analysis must be such that he can tolerate the frustrations of his impulses without responding with some serious form of acting out or by shifting from one pathological pattern to another. For this reason, the psychoses and the addiction states would not ordinarily be regarded as suitable for treatment by psychoanalysis without extensive modification of the usual techniques. Most psychotic patients are excluded from traditional psychoanalysis because of the difficulty they have in forming the affective and realistic bonds which are essential parts of the trans-

ference neurosis which develops during the analysis. Phrased differently, the difficulty can be said to lie in the archaic character of the transferred feelings in such cases. Most patients with addictions are regarded as unsuitable because their ego is unable to tolerate the frustration of primitive impulses which is needed for progress in analysis, with the result that there is frequently an impulsive return to the use of addictive drugs.

There are exceptions, however. Some analysts have found certain alcoholics to be analyzable, depending largely on the nature and intensity of the basic conflicts. And some strides have been made in the analysis of psychotic patients as well, although there have been extensive changes in technique.

Psychoanalysis: Contraindications

The various contraindications to the use of psychoanalysis which have been described at length in the literature seem generally valid. (1) There may be an apparent absence of a moderately reasonable and cooperative ego. Adults over forty, for example, are often considered to lack sufficient flexibility for major personality changes. However, if there are good opportunities for libidinal and narcissistic satisfactions, analysis of patients in their forties or older may have a favorable outcome. (2) The neurosis may be so minor that the expenditure of time, effort, and money in a full scale analysis cannot be justified. (3) A neurotic reaction may have elements of such pressing urgency that there is not enough time to wait for the establishment of a transference neurosis. (4) A patient's life situation may be unmodifiable, on realistic grounds, to the degree that a successful analysis would only result in greater difficulties for him. (5) The analysis of friends and relatives by the same analyst is contraindicated because the many previous points of relationship could seriously cloud the patient's understanding of his current transference responses. It is clear from these various possibilities that, frequently, a short period of trial analysis is the only way to decide whether a patient is analyzable and whether he should be analyzed by a specific analyst.

Psychoanalytic Psychotherapy: Introduction

Obviously, then, psychoanalysis is not regarded as the treatment of choice for all types of psychiatric illness; nor are other forms of treatment merely second best substitutes. There are situations in which analysis is contraindicated, others in which it is unnecessary, and still others in which some other form of psychiatric therapy is the treatment of choice. For some of these situations, psychoanalytic psychotherapy, that is, therapy which is not classical psychoanalysis but is based on analytic concepts, has come to be regarded as a highly respectable set of procedures. Of course, psychoanalytic psychotherapy might also be chosen when, for various practical reasons, psychoanalysis cannot be arranged. In any event,

psychoanalytic psychotherapy is the treatment of choice in a great number of situations, certainly more frequently than is analysis.

Psychoanalytic Psychotherapy: Basis for Therapeutic Intervention

A brief discussion of the diagnostic process and the criteria which should determine the choice of psychoanalytic psychotherapy, as opposed to psychoanalysis, would seem appropriate at this point.

Diagnosis is the foundation of all forms of medical treatment. However, in psychiatric treatment, the initial diagnostic process and the ever necessary alertness to changing diagnostic signals during therapy are many-sided. Such signals would include pathological changes in somatic structure and function, as well as pathological changes in intrapsychic and interpersonal functions. Furthermore, strengths and assets in these areas, as well as pathological factors, must be evaluated. Again, some effort must be made to identify the multiple etiological agents to which the illness can be attributed, ranging from infection and neoplasm, through intrapsychic and interpersonal stress, all the way to the adverse influence of the culture and society in which the patient lives.

The diagnostic process on which the psychiatrist will base his therapeutic intervention in his patient's life must lead to something more than a mere label. That is, the "clinical diagnosis" should include more than the standard phrase used for the group or reaction type of which the patient seems to be an example (according to the moderately acceptable contemporary division of patients into groups or types of reaction). Rather, the diagnosis must include, as well, a comprehensive formulation of the essential issues in the patient's life. Concomitantly, the specialist, when he evaluates his patient's life and problems, should enhance his evaluation by as much precision and understanding as he is capable of. In brief, the effectiveness of psychoanalytic psychotherapy will depend in large measure on the validity of the clinical diagnosis. In outline, it should consist of a general statement, or diagnosis of the dynamics and genetics of the individual patient, based upon adequate study of the somatic, intrapsychic, interpersonal, and cultural aspects of his life.

Psychoanalytic Psychotherapy: Concept of Neurotic Conflict

Further comments about the essential structure of neurotic conflict and of pathological behavior are needed at this point in order to clarify some aspects of the diagnostic process. Once again, an oversimplified dichotomy will be used in making this clarification. Human behavior may be said either to arise from conflict or to be conflict-free. And usually it is behavior, symptoms, or discomfort arising from intense conflict which brings the patient to a psychiatrist for treatment. Notable exceptions do occur, how-

ever. Some patients, for example, do not seem to have enough conflict about carrying their impulses into action. The psychiatrist must be on the alert to distinguish that group from those patients whose seemingly impulsive behavior represents not an absence of conflict, but serious attempts to provoke punishment at the behest of an excessively strict superego.

Intrapsychic components. The basic conflicts of a persistent neurosis are, in general, primarily *intrapsychic*, an opposition between segments of functions of the personality. The conflict usually rages over some force or drive, biological or psychological, which is occasionally—and probably erroneously—called an “instinctual” striving. This drive is unacceptable to other segments of the personality, i.e., to other intrapsychic forces. Or, in another type of conflict, two unconscious strivings of a mutually contradictory nature may be seeking simultaneous expression.

Interpersonal components. However, interpersonal factors may be deeply involved as well. A patient may be seriously at odds with those in his environment in a variety of ways. At times, of course, the conflict with others is actually the manifestation of an intrapsychic conflict on an interpersonal stage. In a character neurosis, for example, the patient may not recognize his intrapsychic problems, because they have taken the form of conflicts with others in his environment or with the world in general. Consequently, whereas one individual may attribute his difficulties to his own illogical need to suffer, for instance, another might attribute them to fate, to “the breaks of the game,” or to bad luck, without ever becoming more than faintly aware of his own part in evoking some of his own bad luck.

In character neurotic patterns of the sort just described, the central problem still seems to be intrapsychic: it stems from an unconscious, pathogenic conflict. In essence, then, the patient who has a neurotic character differs from a patient who has neurotic symptoms, in that he has worked out different “solutions” for his conflicting feelings and drives. The symptom neurotic patient finds autoplasmic solutions to his conflicts; that is, he modifies himself through the formation of symptoms. In contrast, the character neurotic patient has found apparently alloplasmic solutions; but these solutions depend on the persistent distortion of his perception of the world and of the people around him. In other words, to cope with his conflicts, he develops defensive changes in his character structure.

Environmental components. Finally, conflict may be due primarily to the environment. These etiological factors are of great importance in the present context. In some patients, dynamic patterns have been so seriously distorted in the process of development that ego functions which ordinarily play a role in a fairly successful adaptation to the environment remain relatively undeveloped or otherwise distorted. This group would include those patients who are “fixated” at an

oral or dependent level, who have needs or make demands for help from those around them which can never be satisfied or can be satisfied only in part. In their preoccupation with the need to be dependent, such patients may never have developed the techniques of mutual helpfulness; under such circumstances conflicts with the environment are almost inevitable. Frequently, this leads to anxiety and resentment in both the patient and those around him. This group of patients whose capacity to adjust to the environment is impaired also includes some psychotics, e.g., some cases of schizophrenia, some cases with severe affective reactions, and also those with certain character disorders, such as the “as if” characters—those patients whose personalities consist mainly of the scars of old schizophrenic illnesses, to use a somatic metaphor, instead of healthy, growing flesh and blood.

Structural components. These comments about the diagnostic thinking which forms the basis for therapeutic intervention in psychiatric illness stress the need for an understanding of the patient's conflicts and of their solutions. It is imperative to mention also that a reliable diagnostic evaluation requires an assessment of those aspects of the patient's functioning which are free from conflict, as well as an assessment of the areas of conflict. What are the strengths and assets which the patient can draw upon?

A more extensive understanding of some central diagnostic issues can be achieved by a reformulation of the previous comments regarding conflict in the language of the structural propositions of psychoanalytic theory. Again, using a kind of anthropomorphic language to clarify the issues, one can say that in most individuals the id attempts to override the ego or the superego but finds firm opposition, except for brief periods or in limited ways. In impulse-ridden persons, however, the ego is not powerful enough, nor does it have a reliable enough ally in the superego, to stem effectively the strivings which arise from the id. There results a periodic eruption of behavior based essentially on primitive impulses, or on some combination of primitive impulse and defense.

In another group of individuals, the impulses undergo another vicissitude, which is also potentially pathogenic. In these patients the superego and the ego were strong enough, were able to muster sufficient defense, so that essentially the unacceptable impulses remained in the id. But the ego had to deploy permanently large quantities of its defensive forces in the process, forces which might have been put to better use in other ways.

These are only two of the typical patterns of the intrapsychic struggle phrased in structural terms. At other times the relative or absolute strength of the impulses themselves may increase, or there may be a relative or absolute weakening of the ego's defensive forces. One example is the shift of forces seen in adolescence, when the processes of physical maturation

and increased endocrine activity intensify both sexual and aggressive urges. For a time the ego may be partially disrupted by the more urgent strivings. In addition, the ego is faced with the task of finding a new adult identity to take the place of the old childhood identity. The relatively comfortable equilibrium which develops in latency when earlier intense sexual and aggressive strivings are relinquished in favor of sublimation and reaction formation is disturbed to some degree in all adolescents, and to a serious degree in some.

Assessment of the patient's ego strength. The assessment of the strengths of a patient's personality can be expressed in structural terms in a similar fashion. The phrase used most often is "ego strength." It would be of great value in diagnostic work to bring into focus the various ways of estimating the "strengths of the ego," but the concept eludes precise definition although it is indispensable in clinical work.

In operational terms, this concept gives rise to the following questions. What resources does the patient have upon which he can draw in the presence of severe pressure and impacts, both intrapsychic and environmental? Has his development been, by and large, a healthy one? Has he been able to come to terms with life in a genuinely adaptive and fruitful way? Or is he an "as if" personality who has been almost defeated by life (although he may not be aware of his disturbance) and learned to pretend that he is living a more or less normal existence? Or, has he made an even less fruitful adaptation to life?

Many people manage to function successfully for the most part, despite limited neurotic symptoms or character traits, until they are subjected to severe environmental stress. They may then discover that their ego lacks sufficient flexibility and resourcefulness to master the stressful situation to which they are suddenly exposed. Nevertheless, if these persons do not have to endure impacts in excess of the "normal vicissitudes of life," they may never come to the attention of a psychiatrist.

Psychoanalytic Psychotherapy: Definition

What, then, is psychoanalytic psychotherapy? It is psychotherapy which is based on valid psychiatric diagnosis and on psychoanalytic formulations. The diagnostic work-up should give the therapist an understanding of the patient's major conflicts and permit an evaluation of his areas of ego strength and weakness. Psychoanalytic psychotherapy also takes into consideration, insofar as it is possible to do so, the available information about a patient's historical development, especially his relationship with the crucial figures of his childhood. Essentially, the frame of reference developed by psychoanalytic theory provides the coordinates by which the patient's behavior may be evaluated.

In contradistinction to its use in this discussion, the term "psychoanalytic psychotherapy" is often used to

designate a fairly delimited form of treatment, a variety of intensive insight therapy. When it is used in this sense, psychoanalytic psychotherapy differs from analysis in that only limited sectors, rather than the patient's total personality, may come under the scrutiny of the therapist and his patient.

For purposes of this discussion, however, the term is used in a broader, more generic sense to indicate a continuum of therapies which utilize dynamic understanding of the patient based upon psychoanalytic findings and theories. When the term "psychoanalytic psychotherapy" is used in this broader sense, it becomes possible to see that various other psychotherapies, e.g., "brief psychotherapy," "superficial psychotherapy," "deep psychotherapy," and "intensive psychotherapy," differ only in specific details from one another but share in common a broad base of psychoanalytic understanding.

For a number of reasons, there is much interest in shortening the course of psychotherapy; the psychiatric literature includes numerous reports of experimentation with the use of a limited number of interviews for the focal treatment of an acute problem. Patients who respond best to this approach generally are reacting to some acute environmental stress or to a recent shift in internal dynamics. However, the treatment techniques employed are no different, in principle, from the techniques discussed in this section. There is little agreement among psychiatrists as to the criteria which determine whether or not the psychotherapy is to be considered as brief. Some argue that any treatment which takes less than 6 months is "brief"; others consider a course of six interviews a good working format for brief psychotherapy. In addition, some brief psychotherapies utilize a 15- or 20-minute "hour," instead of the more traditional 50- or 60-minute "hour."

The term "superficial psychotherapy" is taken to mean that the therapy does not have as its technique and its goal the bringing of unconscious material into consciousness. Nor, in the best sense of the word, does "superficial" psychotherapy imply superficiality of the therapist's attempts to understand his patient; rather, the term refers to the modest and limited goals of treatment. By way of contrast, therapies which aim at making the unconscious conscious may be referred to as "deep" psychotherapies. Classical psychoanalysis is the paradigm of deep psychotherapy in that sense. Another antonym of "superficial" psychotherapy is "intensive" psychotherapy.

According to the emphasis placed upon the use of free association, psychotherapies may be classified as "directive" or "nondirective." There is less utilization of free associative techniques in directive treatment than in nondirective treatment.

Unlike analysis, which has as its ultimate concern the uncovering and subsequent working through of infantile conflicts as they may arise in the transference neurosis, psychoanalytic psychotherapy takes as its

focus current conflicts and current dynamic patterns. Unlike psychoanalysis, which has as its technique the use of free association and the analysis of the transference neurosis, psychoanalytic psychotherapy uses interviewing and discussion techniques which use free association much less frequently. Finally, unlike analysis, the work on transference in psychoanalytic psychotherapy will usually be limited to a discussion of the patient's moderately superficial transference reactions toward the psychiatrist and toward others.

Psychoanalytic Psychotherapy: Guidelines

The focus and scope of psychoanalytic psychotherapy might best be described in terms of the following hypothetical situation. A patient presents himself for treatment. Thorough somatic studies have been done, and the chief issue is found to be a specific psychological conflict and its manifestations, for example, anxiety attacks. Diagnostic study indicates that the conflict seems to be of recent origin and current. But in it, perhaps, can be discerned the long term patterns which were the patient's typical response to older, infantile traumata. The job of the psychiatrist is to plan a therapy with the goal of achieving enough progress so that the conflict will not interfere with the patient's over-all adaptation.

In some cases, when there is little impairment of the ego, and when other conditions are favorable, the prescription for intervention might be to attempt a basic resolution of the conflict itself. For this, in suitable cases, psychoanalysis would offer the best chance of success. But the patient may not have adequate personality resources for psychoanalysis. Or he may need more supportive comments than are advisable during analysis. Or his problem might seem less serious and possibly more superficial than the problems of many others. Or he may have a history of rebounding quickly from partial neurotic decompensation. Or conversely, his problem may be so serious and so urgent that there is no time for the slow and gradual processes of analysis. Then, the psychiatrist must throw his weight behind one or more components of the conflict, so to speak, or try to foster a new and more effective solution. The psychiatrist may work intentionally toward strengthening the defensive forces of the ego or superego, in order to lessen the strivings which are seeking expression and which are stimulating conflict and anxiety.

At other times, the psychiatrist's course of action will be analogous to the incision and drainage used by a surgeon in the treatment of an abscess. If he can decide where the abscess is pointing, and if he has gained the patient's trust to some degree, as has the surgeon in a different dynamic situation, the psychiatrist may perform an "operation" equivalent to incision and drainage, by an incisive comment. Or by a leading comment based on incisive understanding, he may bring to the surface for discussion some pathological material which has been conscious or precon-

scious. Concurrently, there may be a limited attempt to arrive at insight into conscious and preconscious dynamic patterns (but almost never into deep unconscious patterns).

Or, again, a patient may have lost his bearings temporarily as the result of some difficult emotional problems. With a moderate amount of direction, support, and clarification of the issues by the psychiatrist, the patient may be able to make his own way again without much difficulty. Situations of this kind clearly call for something other than psychoanalysis.

A report by J. Norton on the treatment of a patient dying of cancer illustrates some features of psychoanalytic psychotherapy as discussed in this section. The treatment of the dying patient, as reported, involved maneuvers which are not part of psychoanalytic technique, but the therapist was guided in her choice of maneuvers by an understanding of the patient in the light of psychoanalytic findings. For example, regression was fostered, not for the sake of later interpretation, but for its own sake. It had value to the patient if it could mean greater security without too much hostility or anxiety, or if the hostility and anxiety generated by the regression were met by appropriate responses from the therapist, which would not increase the anxiety but would alleviate it.

Flexibility of psychoanalytic psychotherapy.

The concept of psychoanalytic psychotherapy provided in this section certainly does not exclude such measures as the use of psychotropic drugs. In fact, the use of such medication would be indicated for specific kinds of patients. Nor does it exclude the use of electroshock therapy or other legitimate somatic methods. In fact, psychoanalytic understanding, interdigitated with psychopharmacological and neurophysiological understanding, provides a set of coordinates by which somatotherapeutic methods, as well as psychotherapeutic methods, can be considered in the management of a particular patient. This is in accordance with general trends. As biological and psychobiological understanding are being coordinated with the understanding derived from cultural anthropology and other social sciences, an increasingly reliable basis for theory and for practice is evolving.

Flexibility of technique and adaptability to the patient's needs can be emphasized in psychoanalytic psychotherapy, whereas the analysis of genetic sources can be emphasized in psychoanalysis. In this conception, psychoanalytic psychotherapy can range from a single supportive interview centering around a current but pressing problem to many years of treatment with one or two interviews per week. In contrast to psychoanalysis, a list of disorders treated by psychoanalytic psychotherapy would cover a major portion of the field of psychopathology.

Treatment techniques. One point of difference from classical analysis is that psychoanalytic psychotherapy does not involve the use of the couch. The reason can be stated simply. The stimulation of tem-

porary regressive patterns of feeling and thinking, of high value in psychoanalysis, is much less appropriate in psychoanalytic psychotherapy, with its greater focus on more current dynamic patterns.

Generally speaking, in psychoanalytic psychotherapy, the patient and therapist are in full view of each other, in contrast to analysis, where the analyst is out of sight or at least out of the line of vision. The fact that the therapist is in the patient's line of vision in psychoanalytic psychotherapy may make him seem a more real person, and less a composite of projected fantasies. Furthermore, since psychoanalytic psychotherapy has a strong focus on the current dynamic patterns which are causing the patient difficulty in his extratherapeutic life, transference responses to the therapist are not inclined to become so intense as in an analysis.

Transferences in psychotherapy. Nevertheless, transference attitudes and responses to the therapist may arise from time to time and can be used productively. Spontaneous transferences in the therapeutic situation may give valuable clues about the patient's behavior in extratherapeutic situations, and at times about his childhood. In this way, too, they may inform the therapist about what probably is in focus for the patient at any given time, within or outside of the treatment relationship.

Another dichotomy may be formulated in this connection. The central focus of psychoanalysis is the analysis of transferences to the analyst. The central focus of psychoanalytic psychotherapy is the analysis of the patient's problems with other persons and within himself. The analysis of the transferences to the therapist often is a peripheral matter. If, during the course of therapy, it becomes necessary to interpret some transference strivings toward the therapist, an interpretation away from the therapist which says in effect, "now we can understand better what it is you are doing with your boss (or your wife, or with some other person) because we have seen it operate first-hand here in the treatment," can be of great value. By placing the emphasis away from the patient-therapist axis, the therapist can lessen the possibility of the development of an unmanageable or unrecognized transference neurosis.

In practical clinical work, the analyst and the psychiatrist are confronted daily with many exceptions to these simple dichotomies. In a psychoanalysis, it is necessary at times for the analyst to intervene in his patient's life in a very real way, i.e., not via interpretation of resistance and fantasy, but, for example, through the setting of appropriate limits, or in seeing to it that his patient has medical care which is very urgent but which cannot be sought spontaneously by the patient because of his neurotic problems. And the psychotherapist at times must work "in the transference" to convince his patient of the inappropriateness or the unrealistic quality of his strivings. But the analyst does not regard reality intervention as a

major focus of his work with his patient. Nor does the psychotherapist, however much he may know about psychoanalytic theory and about transference phenomena, deliberately set about establishing a transference neurosis.

In this regard, a word of caution about the transference neurosis in psychotherapy is indicated. An inexperienced psychotherapist, guided by the concept that patients must relive their past experiences in the treatment situation, may stimulate prematurely the unconscious strivings of his patient. Usually, the patient will break off treatment. Only when a good psychotherapeutic relationship has been established should there be even the kind of minimal focus on the transference that has value in psychoanalytic psychotherapy.

Psychoanalytic Psychotherapy: Types

In summary, then, the psychotherapies can be viewed as a sort of continuum, overlapping and complementary. At one end of the continuum would be the hypothetical "pure," "orthodox," "classical" psychoanalysis, with its emphasis on undoing of repression and recovering of past traumatic experiences and feelings. At the other end of the continuum is supportive therapy and perhaps a suppressive therapy. The middle of the continuum would consist of varying mixtures of "insight therapy" and ego-oriented exploration of present day difficulties, of which good psychoanalytic psychotherapy and good psychiatric social casework might be considered paradigms. There is some consensus as to the techniques used at the two ends of the continuum—about supportive therapy at one end, and about the conduct of a psychoanalysis at the other end. But in the central area of the continuum, extending far to the right and far to the left, the rules which govern procedure are less clear, except for some of the general considerations which have been mentioned above. And stating it in more positive terms, one of the points of view of this section is that, ideally, the therapeutic prescription at any position in the continuum is based upon sound dynamic diagnosis, which then points toward the necessary treatment.

The various types of psychoanalytic psychotherapy cited above are described in further detail below.

Insight therapy. This term is used at times for psychotherapies which stem from approaches other than psychoanalytic theory. In this section, however, the phrase is used to describe a type of psychotherapy based essentially on psychoanalytic understanding.

Insight therapy is the first to be discussed in this section for several reasons. The most general reason is that a productive response to psychotherapy is one step forward in human growth and development in which the phenomenon of insight may be a central component. The achievement of insight into the world around him and into himself is one of the great achievements of Man as a species, and as a biological and a culture-oriented organism. He has come to know that a stringent, critical but affectionate self-scrutiny,

as well as an outwardly directed scrutiny, can lead to a greater development of science, and of the growth of an individual and his creative potential.

There are other reasons for placing insight therapy first in this series. In the development of the individual, new insights, independent of psychotherapy, are of high value. Also, as part of psychotherapy, new and accurate insights can be very valuable steps forward. Finally, the concept of insight is a useful tool in the delineation of types of psychotherapy.

After this series of emphatic positive statements about insight, a comparable emphasis must be placed on the fact that insight (by the patient) is not a *sine qua non* of psychotherapy. (In Norton's treatment of the dying patient, for example, the development and use of insight by the patient was not a goal.)

Nature of insight. The exact nature of the phenomenon of insight is not fully understood. Terms such as "emotional insight" and "intellectual insight" have some value, as do the terms "ostensive" and "nominal insight." Using the language of the topographical proposition in psychoanalysis, the following comments may clarify part of the issue. A new perception and registration of an item of psychic content may occur in the preconscious as part of the experience of listening to an interpretation. This fresh preconscious registration may correspond closely to the registration in the unconscious of the pattern just interpreted. But the interpretation may not have produced a connection between the two representations. This limited effect would lead to intellectual or nominal insight. In another instance, however, when the interpretation does lead to a connection between preconscious and unconscious, it may have provided the new link which is basic to the undoing of repression. This more extensive effect would be emotional or ostensive insight.

Richfield's distinction between ostensive insight, which involves a direct experience with a phenomenon, and nominal insight, which involves an indirect notion of a phenomenon, is useful. An individual can have ostensive insight into some of the effects of alcohol if he takes a strong cocktail before dinner and is affected by it. He knows then from personal experience what it is like to be slightly intoxicated. But it is not necessary to be bitten by a cobra to know that its bite is dangerous and that it is good policy to avoid close contact with cobras. Richfield's contrast of two kinds of insight complements the more usual distinction between emotional and intellectual insight, and the distinction between the limited process of a new registration in the preconscious and the process of the undoing of repression.

In a discussion of insight psychotherapy as a variety of psychoanalytic psychotherapy, it is important to specify the area or level of understanding or experience about which insight is to be achieved by the patient. The emphasis of the psychiatrist in such therapy is on the value to the patient of gaining a

number of new insights into the current dynamics of his feelings, his responses, and his behavior, primarily in his current relation with other individuals. To a lesser extent, the emphasis is on the value of developing some insight into his responses to the therapist and into his responses in childhood. (This emphasizes the centrifugal interpretation of transference in psychoanalytic psychotherapy mentioned above.)

Such insight may be emotional and ostensive, or be intellectual and nominal. Emotional and ostensive insight often is much more productive than is intellectual and nominal, but the value of intellectual and nominal insight into dynamic patterns should not be minimized. Even in psychoanalysis, in the analysis of the transference neurosis, it is probable that intellectual insight comes long before emotional insight. The accumulation of many intellectual insights often lays the groundwork for emotional or "true" insight. "The voice of the intellect is a soft one," wrote Freud, "but it does not rest till it has gained a hearing. Finally, after a countless succession of rebuffs, it succeeds."

Indications. Insight psychotherapy is the treatment of choice for a patient who has fairly adequate ego strength to bring to bear on his problems, but who for one or another reason should not or cannot have an analysis. A typical example of a good candidate for insight therapy, rather than psychoanalysis, would be a young man, a college student, who is experiencing difficulties in his academic work and in his relations with women. The psychiatrist may understand diagnostically that there are one or several infantile conflicts still active which are molding the student's current reactions. The psychiatrist may make the diagnosis, also, of a developmental crisis—perhaps the transition from adolescence to adulthood. His prescription for his student-patient would take into consideration the probability that his troubles, although they seem urgent, will tend to resolve themselves more or less spontaneously, at least the developmental segment of the problem. But he recognizes the fact that while the student waits for time to exert its beneficent effect he may be slipping into deeper trouble, academically or otherwise, because of the unconscious conflicts which have survived in active form from his childhood. Psychoanalysis might be recommended. But if the student is to leave the city as soon as he finishes college, or would leave the city if he failed to continue in college, a psychoanalysis would not be feasible. Then the recommendation would be for psychoanalytic psychotherapy, with an emphasis on insight into the current forms of the old dynamic patterns, on their impact in his life, and on alternative attempts at solution.

Effectiveness. The effectiveness of the therapy obviously would not depend solely on the insights developed or used. The patient's therapeutic response would be based on other factors as well, for example, on the ventilation of his feelings in a nonjudgmental

but limit-setting atmosphere, on his identification with the therapist, and on other factors which can be included under the rubric of "relationship." Essentially, the new and productive relation with an older adult could be of great importance in helping him deal with that portion of his problem which centers around his maturing from adolescence to adulthood. This may include a progressive freedom from unrealistic inhibitions, the development of more secure inner controls over impulsive behavior, and a greater trust in his own ability to respond to his own impulses as well as to other individuals in ways that are acceptable to himself and to those with whom he wants to live.

A therapeutic relationship does not require an indiscriminate acceptance of all that a patient says and does. In fact, the therapist stands for long term as well as short term values, for the reality principle as well as the pleasure principle. At times, it is necessary for the therapist to intervene on the side of a relatively weak ego by giving unmistakable evidence of his expectation that the patient will try seriously for a better level of adjustment, or by setting realistic limits to the patient's maladaptive behavior. In doing this, the therapist in turn will try sincerely to be guided essentially by his dynamic assessment of the situation, as in his estimate of a "relatively weak ego," and not to be influenced by his own counter-transference responses.

Corrective emotional experience. One aspect of insight therapy can be discussed in terms of the concept of a corrective emotional experience. Inevitably, the attitudes of the therapist and his responses to the patient and his ideas and impulses are different from those of important figures in the patient's childhood. Hopefully, the therapist's responses are more suitable, more mature, more realistic, and potentially more productive. At times, the therapist, using his knowledge of the attitudes of significant figures in the patient's past life, discusses the differences between their attitudes and his own. The patient may come to see that he had generalized his parents' attitudes as being universal and had generalized his own responses to his parents' attitudes so that they became automatic responses to all parental or older figures. As an example, if the psychiatrist knows that his patient's parents most often were excessively lenient, and if the psychiatrist during the period of treatment has been unafraid to set appropriate and realistic limits when they were needed, he then can discuss and clarify the differences in his attitudes from those of the parents and can discuss the patient's current responses in terms of the differences. In such a sequence, there can be corrective emotional experiences for the patient as well as increased insight into his automatic patterns toward crucial figures in his current life.

The emphasis of the last paragraph was on faulty adaptive behavior which had its genesis in the pathologic aspects of the behavior of the parents. But it is clear from the data of psychoanalysis that even if

parents are ideal, the fantasies which their children usually have about them may have pathogenic potential. This, in fact, was one of the major discoveries of Freud, who found that the hysterics he treated had very rarely been involved in actual incestuous relationships with their parents, as they seemed to recall—that, instead, they had had fantasies, conscious or unconscious, which were of the utmost importance in the formation of their neuroses. So at times, the techniques of insight therapy and corrective emotional experience can focus on the effect of pathogenic fantasies about the figures of childhood. The patient who, as a child, did not distinguish fact from fancy to a sufficient degree can now, as an adult, see that his own hostility is not met with counter-hostility. From this he may realize that his own hostile impulses or fantasies are not so dangerous as they seemed, that parents or parent figures are not so unfriendly as he fantasied, and that he no longer need identify with an image of a parent whom he had imbued with hostility as a child.

Value of insight. Returning to the question of the nature of the insight which can be reached through psychoanalytic psychotherapy, it seems true that a patient can reach some degree of both kinds of insight, intellectual and emotional (to use only these terms for simplicity) during his therapy. The insight may not have been gained by direct perception and understanding of the infantile nature of the feelings and strivings toward the therapist. But the value of the insight can still be high enough so that, when the period of stress is over, additional work may not be necessary. This type of intellectual and emotional insight, even though it seems limited and superficial, may be sufficient to tide the patient over until the equilibrium with his environment is more favorable. He may learn to avoid the cobras of life, so to speak, without ever fully knowing why. If he can avoid them until his maturation brings him to areas where the cobras are fewer and farther between, his partial insight will have served him well.

Effect of transference. The above picture of a typical insight psychotherapy is too simplified. It will be complicated frequently by spontaneous strong transferences to the therapist which threaten at times to disrupt the treatment. These may occur even when no mistake seems to have been made by the therapist. He may not have played a part in evoking the transference reactions through the fostering of regression, or through deep interpretation of dreams, or through conveying to the patient the impression that the therapist expects the patient to have strong transferences as part of the treatment.

But a psychiatrist capable of a firm but affectionate scrutiny of himself will wonder if he has played a part in the development of a transference response which is too intense. His goal will always be development of greater skill in knowing what to say and when to say it. In this connection, a moderately good rule

of thumb is that the therapist should discuss transference chiefly when such transference seems to block the patient from continuing his frank and open discussion of his experiences, his feelings, and his problems.

In addition, transference manifestations occasionally can be pointed out, discussed, or dealt with in some other ways, even when they are not blocking the progress of the psychotherapeutic interviews. The manner in which this is done, if it is to be done, depends on the training of the psychiatrist. If he has had good training in psychoanalysis as well as in general psychiatry, he may decide occasionally in the course of a psychoanalytic psychotherapy to deal for a limited time with transference material essentially as he might deal with it in psychoanalysis. But if he has not had thorough training in psychoanalysis, he should not burden himself with the complexities that would appear if he attempted to deal with the infantile sources of the transference. He nevertheless can deal effectively with the significance of the transference as it throws light on the patient's contemporary life and problems, with only limited reference to his childhood. Such an emphasis on contemporary dynamics, even though it seems to minimize in practice the role of genetic factors, can be a significant part of the treatment process.

Supportive therapy. This is another phrase which needs qualification. It is used as if it referred to a separate and distinct entity, but it only means that there is greater emphasis on support than on other processes. Probably all psychotherapies have elements of insight, support, and relationship, but they differ chiefly in the relative emphasis and priority which the therapist gives to each element. As has been emphasized repeatedly regarding the other therapies discussed, supportive psychotherapy must be individualized and based on an understanding of the specific patient.

The goal of supportive therapy is a limited one. It offers support by an authority figure during a period of illness, turmoil, or temporary decompensation. It has the goal of restoring or strengthening the defenses and integrative capacities which have been impaired. It provides a period of acceptance and dependence for a patient who is acutely in need of help in dealing with his guilt, his shame, or his anxiety, and in meeting the frustration or the external pressures which have been too great for him to handle.

Supportive psychotherapy is of value in psychiatric conditions such as these: relatively mature individuals with limited symptoms based largely upon severe environmental pressures; individuals who, in general, have made a rather good adjustment and are in what seems to be only a temporary period of pressure, turmoil, temptation, or indecision; individuals who have been fairly responsible and supportive toward others in their life adjustment, but who now are required to give beyond their psychological means and

need to be given *to* so that they will have more to give in turn; individuals who are extremely resistant to expressive or insight psychotherapy and those who seem too sick to respond to expressive psychotherapy; and, finally, patients who have no drive toward a fundamental change in their adjustment and are essentially interested in a restoration of a more comfortable previous adjustment.

Techniques. Supportive psychotherapy uses such measures as a warm, friendly, strong leadership; a gratification of dependency needs if that can be done without evoking undue shame; support in the development of legitimate independence; help in the development of hobbies and of pleasurable but nondestructive sublimations; adequate rest and diversion; the removal of excessive external strain, if that is a productive step; hospitalization when it is indicated; medication which may alleviate symptoms (and often does more); and guidance and advice in current issues. It uses those techniques which may make the patient feel more secure, accepted, protected, encouraged, or safe, or less anxious and less alone.

However, this relationship must be handled with extreme skill and care. In the earlier discussion of other therapies, the dangers inherent in a mishandling of the transference have been emphasized. In supportive psychotherapy, one of the greatest dangers lies in the possibility of fostering too great a regression and too strong a dependency. From the beginning, the psychiatrist must plan to work persistently and with good timing toward weaning the patient to a resumption of a greater independence. But it must be added that there are some patients who require supportive therapy indefinitely, often with the goal of maintaining a marginal adjustment outside a hospital.

In supportive psychotherapy the verbalization of unexpressed strong emotions may bring considerable relief. The goal of such talking out is not necessarily or primarily that of gaining insight into the unconscious dynamic patterns which may be intensifying his current responses. Rather the reduction of inner tension and anxiety may result from the expression of emotion, and its subsequent discussion, and may lead to a greater insight and objectivity in evaluating a current problem.

Values of supportive therapy. This type of therapy is often regarded as less exciting, less dramatic, less interesting than is therapy directed more toward insight. But support of the patient when it is appropriate is certainly consistent with some of the best traditions of medicine. And supportive psychotherapy, correctly used, is of great value and is a rewarding experience for the psychiatrist who uses it. This is one of the several kinds of help for which the psychiatric social case worker, by training, is well equipped to offer to many patients. Also, the physician who is not a psychiatrist often can do this form of treatment effectively, although he usually is limited in what he can accomplish because he does not have knowledge

and training enough to make an accurate and full diagnostic assessment of his patient's emotional needs. This situation has been improving remarkably in recent years, because psychiatric training for nonpsychiatric physicians has been increasing in scope and quality.

Relationship therapy. This treatment stands somewhere between the supportive therapy just described and the expressive techniques which characterize psychoanalysis and other types of insight psychotherapy. It not only aims at a restoration of the *status quo ante*, but to some extent aims at a change in personality patterns and at a decrease in vulnerability to external pressures. Relationship therapy contains strong elements of support, and, in a way, it may be considered as a protracted form of supportive therapy, with deeper dimensions. But its methods and its goals are somewhat more complicated than those involved, for example, in supporting a fairly well adjusted person through some current crisis. Relationship therapy may grow out of the therapist's dissatisfaction with supportive therapy and a conviction that his patient may profit from a broader experience. He may want his patient to obtain more from the therapy than dependency gratification and the security and reassurance that comes from feeling accepted, supported, and sustained. Consequently, he may choose a relationship therapy, including in his psychotherapeutic approach more than support, more of the many attitudes which would characterize the helpful reliable parent or older sibling.

This therapy can be described as a fairly prolonged period of contact between a patient and a therapist in which the therapist can maintain, without too much conscious effort, a productive psychotherapeutic approach. The patient responds in various ways, and there develops an interplay of feeling, of communication, and of new experience. Certain therapeutic experiences occur for the patient, such as acceptance as worthwhile or potentially so; of the absence of condemnation or rejection because of defensive distortions; of an identification with some of the more successful achievements and adjustments of the therapist as they may fit his own needs; and of spontaneous corrective emotional experiences as a result of the therapist not responding in the neurotic fashion expected by the patient.

The therapist is interested in the dynamics of a patient's problems, but he is more interested in fostering a good therapeutic relationship. The cornerstone of that relationship is that the therapist's fairly consistent attitudes toward the patient are like a composite of those attitudes of a good, deeply helpful, father or mother, or of a good, deeply helpful, older brother or sister.

Advantages of relationship therapy. In this approach, the psychiatrist is not so much "treating" the patient as "rearing" him or providing the setting in which the patient can "rear himself," can grow and

develop. For this reason, relationship therapy often is recommended for patients who are in some sort of developmental turmoil, such as the transition from adolescence to adulthood, at whatever chronological age the change may occur.

Relationship therapy provides the therapist with frequent opportunities to behave in a fashion different from the destructive or unproductive portions of the behavior of the patient's parents. At times, such experiences seem to neutralize or to reverse some of the effects of his parents' mistakes. If the patient had overly authoritarian parents, the therapist's friendly, flexible, nonjudgmental, nonauthoritarian, but at times firm and limit-setting attitude, provides the patient with opportunities to adjust to, be led by, and identify with a new type of parent figure. In a similar fashion, patients who had overly indulgent, overly seductive, overly passive, or overly inconsistent parents now can begin anew, in a sense, brought up again by a parent figure who is not making the old mistakes and who is responding in a way palpably different from the patterns of the parents, or from the patient's fantasies of the patterns of the parents.

Therapy as a corrective emotional experience. Such an experience in a relationship therapy is one kind of corrective emotional experience. In this form, it is not associated with the type of clarifying discussion that may be used in insight psychotherapy. There are several misconceptions to be avoided in the use of the concept of the corrective emotional experience. It is better not to define it or to characterize it as involving a deliberate role playing on the part of the psychoanalyst or of the psychiatrist, although this impression might be gained from a perusal of the literature. Also, it should not be interpreted as implying that a corrective emotional experience is to be used in a psychoanalysis as a substitute for the analysis of the transference neurosis. Rather, a productive, workable, and reliable conception of the corrective emotional experience is that in psychoanalytic psychotherapy, the psychiatrist, with little or no role playing, can work toward his patient's having a number of corrective emotional experiences, some with insight and some without. Thus limited and defined, the corrective emotional experience becomes one of the fundamental techniques leading to therapeutic change.

With this approach, there is no danger that the corrective emotional experience will be used as a substitute for an analysis of the childhood roots of the transference. In psychoanalysis, the primary emphasis is upon the analysis of the infantile sources of the transference through a study of the transference neurosis. Corrective emotional experiences are not emphasized, although they may occur as one possible effect of the analytic work. But in psychoanalytic psychotherapy, there is little or no analysis of the infantile sources of the transference; and so the corrective emotional experience can be used freely, whenever it is indicated, as a therapeutic technique. It should perhaps be added

that in an analysis, if the analyst deliberately or artificially alters his usual behavior toward his patient in order to provide his patient with a corrective emotional experience, he runs the risk of making the transference neurosis unanalyzable by him. However, a full discussion of this technical matter goes beyond the scope of this section.

Suitable situations for relationship therapy. Relationship therapy is suitable for a variety of psychogenic illnesses. For example, it may be useful when a patient is very resistive to expressive psychotherapy or is considered too ill for such a procedure. It may be chosen when the diagnostic assessment indicates that a gradual maturing process based on the elaboration of new foci for identification can be regarded as the most promising path toward modification.

Relationship therapy, with the addition, when possible, of attempts at insight therapy, can form the backbone of the work of many psychiatrists. It may constitute a significant portion of the work of many psychiatric social workers, psychologists, and others. Possibly it can provide the best line of approach for the growing group of internists and other physicians whose psychosomatic and other medical interests call for the development of delimited techniques of psychotherapy.

Psychoanalytic Psychotherapy: Dynamics of Cure

In the discussion of psychoanalysis earlier, the techniques which foster the therapeutic, controlled, yet extensive regression characteristics of the transference neurosis were considered. Among those factors were the physical setting of the analytic situation itself, with the use of the couch; the high frequency of the interviews; the lack of a time pressure in an analysis; the emphasis on the discovery and interpretation of unconscious, historically determined dynamic patterns; and the use of techniques of dream interpretation which go below the surface of the manifest content.

Psychoanalytic psychotherapy can be examined in the light of these factors. The point has been made that the emphasis in psychoanalytic psychotherapy is more on current dynamic trends than on genetics, and more on the understanding of contemporary relations and dynamics than on the understanding of the transference, although it includes a productive consideration of significant nonlogical attitudes and responses toward the therapist.

But unlike psychoanalysis, in which a limited regression and dependency may be encouraged because of their value in work which will lead to maturity, progression, and independence, psychotherapy in general tends to discourage regression and dependence except in those special circumstances in which the need for support is great, either for a brief period, or more rarely for a long period.

The techniques which foster independence and pro-

gression in psychoanalytic psychotherapy are of two kinds, which can be called the techniques of commission and the techniques of omission. Included in the techniques of commission are interpretations according to the centrifugal principle (away from an emphasis on genetic transference interpretations). Also included is the creation of a supportive, collaborative relationship which clearly carries with it the expectation of growth and maturation. Included in the first group (of moves which foster independence) is the psychiatrist's willingness to interact with his patient, to be seen in his functioning as a real individual.

The second group, techniques of omission, are the moves which are to be avoided in order to prevent the fostering of dependence and regression. These moves stem from a misapplication of the "analytic model," from an unfortunate attempt to make psychotherapy into a kind of psychoanalysis rather than a psychoanalytic psychotherapy. Basic to this mistake is an exaggerated belief in the therapeutic value and power of release from repression, under almost any circumstance, and an associated mistake of a serious overemphasis on the value of deep "insight," again under almost any circumstance. From these mistakes follow certain incorrect moves or techniques which are to be avoided: the therapist's comments to the patient about symbols in the patient's material, even when the symbols cannot be related easily and obviously to current material; the interpretation of the latent dream content rather than of the manifest. It is clearly not necessary for a therapist to disclose to his patient everything he has been able to deduce about him. In addition, through a curious negative twist, there may be a phobic avoidance of a transference interpretation when it is genuinely needed to unblock progress.

One complication of analytic psychotherapy (and of psychoanalysis also) is that therapy—even supportive therapy—may become a way of life for a patient. This at times may be a manifestation of uncontrolled or uncontrollable regression. Some patients, of course, whose egos may be such that they are unable to stand alone and in all likelihood never will be able to, may need permanent supportive treatment. But most often "therapy interminable" seems to result from a subtle interplay of silent transference and counter-transference factors, with the therapist finding unconscious gratification in fulfilling some of the many parental roles for his patient, who in a complementary fashion finds the reenactment of childhood or the apparent fulfillment of ungratified childhood wishes only too seductive.

In addition, if intense transference responses appear without adequate preparation, a sort of "wild analysis" or "wild psychotherapy" may result. Usually, the patient then will break off treatment, convinced either that his therapist has problems more severe than his own, or that psychotherapy is just not for him.

Another problem can arise. Some inexact interpretations can be a comfort to the patient to the extent that they permit him to rationalize his own problems, to lessen his anxiety by making a displacement away from prime causes. In this event, a new intellectual idea has been substituted for a possible true insight.

But inexact interpretations have their value. At times they may restore a workable but neurotic equilibrium. At times they are resting places in the search for a more adequate understanding.

Some Miscellaneous Forms of Psychiatric Treatment

In addition to those forms of psychological treatment which utilize chiefly the techniques of the patient's talking and his nonverbal communications and cues, and the verbal and nonverbal responses, comments, clarifications, and interpretations by the therapist, there are certain other forms of treatment which can be conceptualized according to psychoanalytic principles and which should occasionally be included in the psychiatrist's prescription for his patient. These forms of treatment utilize dynamic understanding of the individual patient and his problems, but verbalization and discussion of conflict are not their primary techniques. Rather, they lie in the borderland between psychotherapy—the "talking cure"—on one side, and nonspecific environmental and physiological treatment techniques on the other side. Often, the role of these psychiatric therapies is one of facilitating psychotherapy; but occasionally, as will be shown, they may become central in the treatment plan.

The treatment techniques to be considered here include such methods as environmental manipulation, activity therapies, and bibliotherapy.

Environmental manipulation. At times, removal of the patient from a stressful environment holds the greatest hope for successful treatment, particularly if the patient's condition might deteriorate unless the external stresses are removed or if, at best, the patient would only continue in a fruitless stalemate with external forces.

Vacation. Common instances of this form of treatment range from the recommendation of a vacation for an overworked patient to foster home placement for a child. Once again, however, the recommendation for individualization of the treatment cannot be made too strongly. In the case of a vacation, for example, a seemingly innocuous holiday can become a disaster. A patient might be maintaining his dynamic psychic equilibrium only through such mechanisms as overwork, perhaps out of a guilty need to suffer. To remove the external pressures through a vacation is to risk upsetting a precarious equilibrium; the consequence might be a serious and severe regression or depression instead of the hoped for restorative respite from the stresses of everyday life. An inquiry into the causes of the overworking is often more to the point

than the recommendation that the patient take a vacation.

Hospitalization. Hospitalization is a major form of environmental manipulation which may be called for in the course of some psychotherapies. The psychiatrist will consider hospitalization when his patient shows unmistakable evidence that his customary manner of dealing with his environment has become impaired to such an extent that he has become a danger to himself or others around him. The term "danger" used in this sense refers not only to suicidal and homicidal possibilities, but also to such dangers as the unwise acting out of the hypomanic or manic patient or drug addict, or the life-threatening withdrawal of the catatonic patient. Hospitalization may provide the only setting in which psychotherapy can be effective with those patients; but it may simultaneously seem to the patient to be a defeat, a possibility which might impair his chances of recovery.

Foster home placement. Foster home placement for children is another example of environmental manipulation which requires careful consideration of the complete picture. It is usually undertaken only when careful study indicates that the child would not have an opportunity to form satisfactory healthy identifications in his own home environment and when there is a high probability that that environment will not improve sufficiently in the predictable future. Once again, the risks of intervention are great, and it is often difficult to decide whether or not a child would in fact be better off with foster parents and away from his biological parents.

Activity therapies. The various forms of psychotherapy attempt to work with pathogenic conflicts, in general through facilitating their recognition and verbalization and subsequent integration by the patient. This process requires, most of all, the renunciation of immediate gratification of strong psychological strivings. But there is another possibility for the reduction of psychological tension, that of its direct expression in action. Activity therapies utilize this approach. These are therapies which depend for their effect not upon the verbalization of psychic contents, but upon the reduction of intense and perhaps unacceptable or conflict-filled strivings through active expression of derivative and related drives. In this group are the occupational therapies, recreational, industrial, dance and music therapies, and other forms of treatment. The activity therapies are often used in hospitals; but only rarely are they employed in out-patient psychotherapy, although a psychiatrist might urge his patient to develop a hobby, play golf, or take up bowling.

A basic assumption about the various activities encompassed by occupational therapy is that some activities are more therapeutic than others in specific problems. For example, it is often observed that depressed hospitalized patients seem to benefit from

monotonous tasks which they can regard as demeaning, thereby giving some expression to their wish to suffer in a harmless and even constructive way, refocussing some of their aggression away from themselves and onto their environment.

Process in activity therapy. In all of the activity therapies, and especially in occupational therapy, there is an increasing awareness that it is the process, and not the product of the process, which is of greatest importance. It is more important that a patient *do* leatherwork or *make* a finger painting than that the purse or the picture be of good quality, although that may also be important to the patient. It is possible to have a room full of hospitalized patients silently engaged in dull, repetitive tasks, without a flicker of human interchange among them; such a situation probably would have a low therapeutic value. There is a growing tendency today, however, to utilize occupational therapy for the fostering of better interpersonal relationships between the patients and with the therapists. Many therapists today want to know something of the patient's dynamics and background in order to provide him with occupational tasks which better meet his therapeutic needs.

It also seems likely that a patient will make different uses of occupational therapy at different times during his illness. At one time, it might serve to break into the tedium of an otherwise bleak hospital routine. Again, an occupational task might serve to reduce anxiety through muscular activity. Or at another time, there might be some strengthening of the patient's ego through the mastery of a new skill. Or the occupational therapy might serve as a vehicle for the formation of new interpersonal relationships which the patient needs.

In some hospital settings, where the psychiatric staff is in short supply but long demand, it is possible that the occupational therapist is almost the only person who has some consistent interpersonal contact with a patient. Perhaps the nondemanding occupational therapist in that setting may be sufficiently therapeutic to bring about a reversal of the regressive forces of a psychosis, serving as a preparation for other forms of psychological treatment, including psychotherapy.

Other forms of activity therapy may serve more directly as expressions of conflict components. Here recreational therapy should be considered, in which competitive games, for instance, may give acceptable expression to hostile urges. Also dance therapy, in the form of expressive physical movement, may serve to drain off intense drives. But of greater importance in these therapies is the almost inevitable psychological contact with other human beings which helps to reverse regression.

Even food can be conceptualized as therapy. Almost everyone will treat himself to some favorite food—usually fattening and forbidden—at times of frustration and stress. An analytic patient may have

a rich malted milk before or after an anxiety-laden analytic hour. But the systematic giving of warm drinks and simple foods to a newly hospitalized patient at some time during the admission procedure may be therapeutic in the sense that it helps to establish an interpersonal bridge between the patient and the hospital. It repeats symbolically the earliest mother-child linkage.

Bibliotherapy. A question frequently raised by patients in psychotherapy and in psychoanalysis is: "What should I read to help me to understand myself better?" For patients in psychoanalysis, the answer is usually simple: "There is no homework." This poses a special problem in the treatment of those patients who, by virtue of their work or profession, are required to read technical materials about mental health. Psychiatrists in analytic training or psychiatry residents in psychotherapy or analysis are examples. The reading of technical materials may well become a locus of resistance in those patients; and while the therapist or analyst usually cannot forbid the reading of technical books and articles, he still must deal interpretively with the resistance which that reading serves. For one thing, any article or book about psychiatry is a generalizing statement about a class of people; and its uncritical application to the individual reader is at best a risky proposition. All physicians are familiar with this problem in another context—the tendency of medical students to suffer from whatever disease they happen to be studying this week.

But for some patients, the use of literature for therapeutic purposes, bibliotherapy, does seem to have a limited usefulness. Some persons whose conflicts are not too severe may derive comfort and support from the Bible. Others may gain some limited, though genuine, insight into their own dynamics by reading any of a number of books on mental health. A good marriage manual may be therapeutic for the emotional problems of a marriage if they are not severe.

In yet another sense, the study of literature may have some very real value. Psychiatrists, especially, find much of value for their general understanding of their patients through reading some of the world's great literature. In some psychiatric hospitals, patient groups have been formed for the study of great books; but even here, the question must be raised as to whether the socialization may not be more beneficial than the insights which may be gotten from the books.

Suggested Cross References

For a detailed discussion of the theoretical model of psychoanalysis and psychoanalytic psychotherapy, see Section 6.1 by Mack and Semrad, on Sigmund Freud, in Area C, on current theories of personality and psychopathology. Diagnosis in psychiatry is discussed at greater length in Area E, on assessment in psychiatry. Finally, the several sections included in Chapter 36 in this area of the volume deal specifically

with the role of the environment and occupational therapy in the treatment of psychiatric illness.

behavioral "problems" as quickly as possible, by controlling the learning behavior of the patient. As such, behavior therapy has been described as a new and different mode of psychotherapy by its several proponents. In this section, the major features of its development will be summarized, and the ways in which behavior therapy differs from the more traditional psychotherapeutic approaches will be specified. A brief summary of the techniques employed by various schools of psychotherapy to modify behavior, and the theoretical propositions from which these derive, will provide a useful context for the subsequent analysis of behavior therapy.

Historical Perspective

Control of human behavior. Early in his history man discovered that there were three principal ways of controlling or modifying human behavior (see Figure 1).

First, behavior can be modified by changing the antecedent situational events which precipitate specific forms of behavior (Figure 1a). For example, a child who does poor schoolwork and is a disciplinary problem while he is in a class supervised by a particular teacher may become an effective, cooperative student if he is assigned to a different class with a different teacher. This observation underscores the fact that behavior is a function of the situation in which it occurs. That is, some behavior patterns can be regarded as related to specific situations, since they reliably and consistently occur together.

Second, the kind of behavior which occurs in a particular situation can be changed or modified (Figure 1b). For instance, a child can be taught to engage in constructive compromise activity, rather than throw a temper tantrum, when he encounters a frustrating situation. Particularly important are those instances in which a person's behavior is a result of the way he perceives the situation in which he finds himself. Thus, modification of the method he employs to cope with the situation may be contingent upon the therapist's ability to help him to construe it in a different and more effective way.

Third, the situational consequences to which the behavior leads may be altered, thereby modifying future behavior (Figure 1c). This concept is based on the broader proposition that some types of behavior are learned because they regularly lead to satisfying outcomes, or because they enable one to avoid unpleasant or painful consequences. Thus, when aggressive attacks on others have consistently led to punishment for assaultiveness, hostility may give way to more cooperative attitudes because of the concomitant rewards. Again, a child's fear of dogs may be modified by exposing him repeatedly to satisfying and nonfrightening experiences with animals.

Throughout history, various devices, such as situational manipulation (changing a person's environment), exhortation, advice, persuasion, teaching,

34.2 BEHAVIOR THERAPY

HUGH B. URBAN, Ph.D.

DONALD H. FORD, Ph.D.

As an approach to the treatment of disordered behavior, behavior therapy represents a relatively recent development in the field of psychotherapy. In brief, it constitutes an attempt to alleviate specific

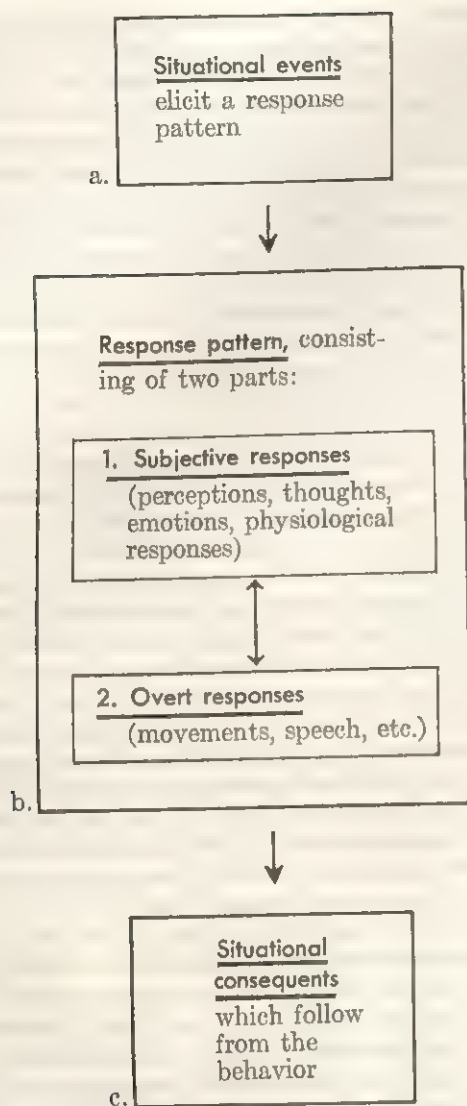

FIGURE 1. Simple model of a behavior sequence, showing the three primary ways of modifying or controlling human behavior.

prayer, reward, praise, punishment, and medication, have been used to influence the behavior of individuals. Each of these procedures emphasizes one or another of the three principal methods of modifying behavior described above. However, despite their general effectiveness, some types of behavior are very resistant to change by these methods, for various reasons. In such cases, the usual procedures do not seem effective, or they may actually exacerbate the problem. For example, motor paralysis, skin rashes, tics, delusions, hallucinations, and various forms of antisocial behavior have often persisted in the face of the most strenuous efforts to change them. In certain situations, neither the manipulation of the situational antecedents (Figure 1a) nor the alteration of the consequences of behavior (Figure 1c) has produced results of any apparent significance.

Traditional Concepts of Behavior

Emphasis on subjective factors. The fact that certain modes of behavior are not affected by common techniques of intervention led Freud and others to conclude that the difficulty lay within the behavior patterns themselves (Figure 1b). However, behavior patterns have two major components. (1) Those responses which are overt and therefore accessible to the observation of others (e.g., muscular movements or talking) are often referred to as behavior proper. (2) A second group of responses are subjective; that is, they are self-observed. This category of responses could include thinking, those aspects of emotion which are not communicated (i.e., feelings), and images. The fact that these components are frequently referred to as aspects of personality rather than behavior may be attributed in large measure to Freud's contention that the difficulty in modifying certain cases of behavior disorder was that this disorder actually resided within the individual's subjective thoughts and the emotions which accompanied them. Accordingly, he focused on certain types of thoughts, which he initially called traumatic memories and subsequently referred to as wishes.

In the realm of psychotherapy, then, the primary emphasis throughout the first half of the 20th century has been upon subjective factors. Freud set the prevailing pattern by delineating the organization of personality and its components (id, ego, and super-ego) and emphasizing the role of these components as primary determinants of behavior. This theme was echoed by those who followed: Jung specified the role played by complexes and drives (and their related thoughts and feelings) in the acquisition and maintenance of behavior. Adler spoke of the apperceptive schema, a network of thoughts and perceptions which the individual develops, and he elaborated upon the fact that the individual's actions are guided by his anticipations of the consequences of these actions (goals and guiding fictions). Rank spoke of will and counter-will as well as fear and guilt, and of dependent orientations as determinants of behavior. And, more recently, these themes have been sustained, with individual modifications, by such theorists as Rogers, Horney, and Harry Stack Sullivan.

Altering subjective events. Consistent with this point of view, within the framework of traditional psychotherapy, efforts have been directed toward the modification of overt behavior by altering the antecedent perceptions, thoughts, and feelings (subjective responses) upon which that behavior depends. Access to these subjective (cognitive, intervening) events has been effected by means of verbal interaction (the therapeutic interview). Efforts are made to change the way a person thinks by getting him to talk about his thoughts. Concurrently, the assumption is made that if a person learns to think and feel differently, he will act differently.

Although the "talking cure" has been preeminent in traditional psychiatry throughout most of this century, it has been criticized on several grounds: (1) the length of time said to be required to produce changes by this method, (2) the limited variety of problems amenable to its application, and (3) the restrictions on the number of individual patients who can be treated because of the time and expense involved, and because of the limited number of qualified practitioners. Moreover, objection has been made to the lack of precision in theory and the variability in treatment techniques which has characterized the field of psychotherapy. These factors are not considered by critics to be conducive to the effective treatment of behavior disorders.

Theoretical Rationale for Behavior Therapy

Eysenck's studies. These criticisms, sporadic but persistent, were crystallized by a group of workers in England. In the early 1950's, H. J. Eysenck, a professor of psychology at Maudsley Hospital in London, reported on surveys of evaluative studies of psychotherapy. As a result of his investigations, Eysenck concluded that, by and large, it could not be demonstrated that psychotherapy had been any more efficacious than other treatment approaches; indeed, in many instances it could not be demonstrated that psychotherapy was superior to no treatment at all.

Although these surveys possessed serious methodological weaknesses, they stimulated the London group to search for another, more effective approach to mental illness. Subsequently, they adopted the idea, urged by others as well, that the field of clinical psychiatry should incorporate the contributions of the basic behavioral disciplines. Since psychotherapy represents a process of reeducation or relearning, why not base efforts to facilitate such relearning on the knowledge about the way humans learn which had been gained in the experimental laboratories? Eysenck and those who have followed his lead have explicitly declared this to be their approach, and the group has coined the term "behavior therapy" to represent this orientation.

Characteristics of Behavior Therapy

Definition. Behavior therapy is best described as an approach, rather than a specific treatment technique. The term behavior therapy was chosen to reflect the emphasis which this group of clinicians places upon the overt, and objectively observable behaviors of patients. In contrast to psychoanalysis and the psychotherapies, which focus on subjective behavior, i.e., thoughts and feelings, and seek thereby to effect changes indirectly in the patient's overt behavior, the behavior therapy approach addresses itself directly to the patient's overt behavior. In fact, it has been suggested that changes in thoughts

and feelings may be effected by changing the way one acts, rather than vice versa.

Thus, the focus of treatment is one of the characteristics which identify the behavior therapy approach. In addition, its treatment procedures derive directly from principles of learning developed in the experimental laboratory. Moreover, an attempt has been made to integrate some of the conceptual precision and procedural systematization of the laboratory into clinical practice.

Theoretical model. In general, behavior therapists have adopted as their theoretical model one of the several variations of psychological learning theories which have been developed in experimental laboratories during the last 50 years. Naturally, different theories as to how learning occurs have had different implications with regard to psychotherapeutic treatment procedures. Thus, those therapists who have followed the lead of Pavlov, Watson, and Guthrie have been guided by conditioning, or conditioned learning theory (Figure 1a), and have emphasized the fact that interrelationships between situations and responses develop as a function of the manner in which the situational stimuli are presented. On the other hand, Thorndyke, Hull, and B. F. Skinner, the leading proponents of reinforcement theory, have been notable in their exploration of the effects of different consequences, positive and negative, in determining which behavior will ultimately be acquired (Figure 1c). Finally, during the past several decades, the personality theorists, such as Allport and Rogers, have emphasized the role played by the subjective aspects of behavior (thoughts, feelings, perceptions, and images), which they have conceptualized, in turn, as traits, attitudes, and predispositional organizations.

Concept of disordered behavior. The behavior therapist regards both neurosis and psychosis as examples of learned behavior. Disordered behavior does not differ in principle from normal behavior. Rather, disordered behavior patterns are viewed as inappropriate or maladaptive habits which have been learned and continue to be maintained in much the same way one acquires desirable habits. They occur in a person's repertoire as a result of repeated exposure to aversive events (and hence are conditioned) and are maintained because they consistently lead to positive effects or make possible the avoidance of deleterious ones. The disordered aspects of an individual's behavior may represent a small or a large part of his total behavior, depending on the severity and persistence of aversive events and other factors. Psychiatric syndromes, then, are merely viewed as collections of faulty habits, interrelated in various ways.

This view is in direct contrast to the concept that psychiatric syndromes are produced by one "central cause" or disease process. The behavior therapist does not assume that inappropriate behavior is the symptom of some underlying disease process or psycho-

logical state, and he explicitly eschews the notion that neurotic symptoms stem from such underlying causes. Consequently, he feels that the focus on "underlying causes," which is characteristic of other theories of psychopathology, has led to a neglect of the presenting problems. Many behavior therapists believe that this misplaced focus has led, in turn, to unsystematic treatment, a failure to specify the problem behavior, an assumption of a "single cause" for the multiplicity of factors involved in inappropriate behavior, and a presumption of a degree of uniformity which is not justified by the data.

Correspondingly, purposive accounts are avoided, and preference is given to concepts which identify the external and identifiable conditions which control the behavior in question. Early learning experiences are regarded as unimportant for treatment purposes, unless the same conditions which were related to the initial acquisition of the behavior continue to be operative. No particular stage of development is characteristically considered to render a growing person more vulnerable to some types of emotional learnings than any other stage.

In summary, the development of behavior therapy has been accompanied by a rejection of the traditional concept of disorder (which is often referred to as the "psychodynamic approach to behavior") and of the techniques which have stemmed from emphasis upon the "inner and underlying determinants" of human behavior.

Treatment Techniques

An armamentarium of treatment techniques has been developed, based on the literature on experimental psychology, which are designed to effect the direct modification of behavior. As mentioned earlier, these techniques derive from different theoretical positions. Consequently, they are often described in different terms and are based on different rationales. However, there are areas of agreement and these will be described briefly.

Goals of behavior therapy. By and large, behavior therapy is problem-oriented. Since psychiatric syndromes are conceived of as collections of faulty habits, it is assumed that these habits can best be modified if they are the direct focus of treatment and are changed one by one. It is characteristic of behavior therapists, in general, to take the presenting problem of the patient as the focus of treatment. To illustrate, if the patient complains of excessive motor and muscular tension, the therapist's efforts are directed toward reducing that tension. And if tension represents his only presenting complaint, treatment will be considered complete when its reduction is effected. Characteristically, no attempt is made to unearth the underlying sources of a given tension; therefore, extensive inquiry to that end is not required. The reconstruction or reorganization of the person's patterns of interpersonal interaction, or modi-

fication of his behavior through awareness and understanding, do not represent major objectives in the treatment process. Consequently, treatment objectives are characteristically much more limited, and perhaps more attainable, than is the case in traditional psychotherapy.

Therapeutic process. On the whole, therapy tends to follow a typical course, as outlined below.

Determination of the behavior to be modified.

Ordinarily, this is accomplished by means of interview, although some investigators have employed questionnaire forms as a means of standardizing and augmenting the patient's self-report. Efforts are made to identify precisely the nature of the patient's complaints with respect to his overt, objectively observable, behavior.

Establishment of the conditions under which the behavior occurs.

Again, primarily by careful inquiry, efforts are made to determine precisely under what circumstances the behavior has been observed to occur, the antecedent associative conditions, and the characteristic consequences of the behavior. If, for example, the patient complains of unaccountable fears, attention is directed to those occasions when he is aware of feeling afraid, as well as those events which typically follow the occurrence of fear.

Determination of the factors which are responsible for the persistence of the behavior. A decision is reached as to whether the patient's response appears to be the result of a simple conditioned fear; whether it reflects an initial fear that has become generalized, so that it occurs in related but different sets of situations; or whether the response seems to persist because of the consequences to which it leads. This analysis is focused on the search for external conditions, antecedent and consequent, which can be considered instrumental in maintaining or controlling the behavior in question.

Selection of a set of treatment conditions. Circumstances are selected which can be deliberately manipulated by the therapist (sometimes called the operator) to modify, counteract, or undo those factors operative in the patient's individual situation.

Arrangement of a schedule of retraining. A retraining experience (consisting of individual units, which are often called trials) is planned, during which the patient's behavior is systematically subjected to modified conditions. Treatment is terminated at the point at which the behavior sought begins to occur at the desired level of incidence.

Techniques for modifying antecedent conditions. Again, the specific methods which have been developed to date are numerous and varied. However, most of the procedures designed to modify antecedent conditions can be encompassed in the classification presented below, which has been adapted from Grossberg's formulations.

The first group of procedures have in common the fact that they are directed toward the *modification*

of the interrelationships between responses and the situations in which they occur (interrelationships between *a* and *b* in Figure 1). These procedures will be referred to by the labels which are employed most frequently in the current literature and are therefore most familiar.

Desensitization technique. In those instances in which an inappropriate pattern of response (such as fear or disgust) has been acquired in relation to a particular object or event, a method of systematic habituation has often been employed. Stimuli which elicit the maladaptive response are selected. The subject is then repeatedly exposed to these stimuli at such low levels of intensity that they do not evoke the complete response pattern. Exposures are then continued at gradually increasing levels of intensity, until even high intensity levels of that stimulus no longer elicit the former inappropriate response. This procedure has been used successfully to reduce exaggerated startle response to noise in military settings. It has also been used repeatedly in the elimination of exaggerated and inappropriate fears, and it has been applied to such problems as feelings of guilt and self-derogation with reported success.

Reciprocal inhibition technique. In certain respects this technique closely resembles the desensitization technique; however, it introduces an additional factor. It is based on the fact that in the human repertoire there are some response patterns which are incompatible with, and antagonistic to each other, e.g., fear and sex, anger and digestion, relaxation and distress. The objective of the procedure, then, is to arrange conditions so that a more appropriate response will occur in relation to the troublesome situation, to replace the subject's maladaptive response. Thus, in those instances in which an inappropriate pattern of behavior has been acquired in relation to a person, event, or object (such as a fear of small animals), efforts are made to elicit another response at a stronger level of magnitude, one which is incompatible with the initial response. Most frequently, this has been accomplished when relaxation as a pattern of response has been pitted against fear. More specifically, patients are trained in relaxation procedures, either by instruction or by means of hypnosis. Conditions are then arranged so that the pattern of relaxation becomes systematically associated with the stimuli which have hitherto elicited fear.

Reciprocal inhibition and desensitization. The two methods described above have often been combined into one treatment program, an innovation which is attributable to Joseph Wolpe, who has become a prominent exponent of the behavior therapy approach in this country. This third, combined procedure has become a widely used and successful form of behavior therapy in the treatment of phobic patterns of response. As the first step in this technique, the therapist establishes a list of the situations which elicit the undesirable pattern of behavior. These are

ranked in ascending order, in terms of the intensity of the response which they elicit. The subject is then trained in relaxation procedures. Following this, he is asked to visualize the fear-inducing situation which stands lowest on the list (the weakest) while he is relaxed. A few trials of desensitization are usually sufficient for the relaxation pattern to occur in place of the fear. The desensitization procedure is then continued up the hierarchy of situations, until the most intensely disturbing situation can be visualized while the patient is relaxed. Usually, the pattern of relaxation which occurs during the symbolic representation of the feared event generalizes to the real-life situation itself. According to individual clinical reports, the entire range of phobias has been successfully modified by this procedure. In addition, it has been reported to have been successful in the treatment of a case of bronchial asthma in which desensitization involved a demanding wife and the antagonistic pattern of behavior employed was assertiveness.

Conditioned avoidance technique. The foregoing techniques have been characteristically used in relation to patterns of avoidance (such as fear or aversion) which are deemed inappropriate in the context in which they occur. When the therapist must deal with patterns of approach (in contrast to patterns of avoidance), the opposite conditions for relearning are established. To illustrate, in those instances in which the patient has learned to seek out persistently inappropriate situations, for example, when he has learned to drink excessive amounts of alcohol or to make homosexual advances, conditions are established in which aversive stimuli (e.g., electric shock or nauseant drugs, such as apomorphine and emetine) are systematically paired with the situational stimuli which elicit the inappropriate response. Thus, for instance, in the treatment of fetishists electric shock is repeatedly associated with the object of their sexual arousal, and conditioned aversion to the formerly attractive stimulus is thereby established. In brief, the procedure is similar to the technique of reciprocal inhibition, but it operates in reverse. Reports as to the success of this procedure in the modification of behavior have not been uniform. It has been used primarily in the treatment of sexual perversions (homosexuality, transvestitism, and fetishism), and with alcohol addiction, and success and failure have been reported with equal frequency.

Techniques for modifying environmental consequences. To move on to the second set of procedures, we encounter those techniques which focus on the *modification of the interrelationships between the responses and the consequences to which they lead* (interrelationships between *b* and *c* in Figure 1). As a result, the therapist's efforts in this area will entail a manipulation of the consequent conditions to which the behavior leads. In general, these techniques fall into two groups. The first group of techniques is directed toward increasing the likelihood that a de-

sired response, i.e., behavior, will occur in those instances in which it is infrequent or absent. Thus, it is employed in those cases in whom the absent behavior (such as the failure to eat, talk, or interact with others), constitutes a behavior deficit. In contrast, the second group of techniques is directed toward producing a decrease in the likelihood that a response will occur because it is considered undesirable, maladaptive, or inappropriate.

Positive reinforcement. In those instances in which a necessary or desired response occurs infrequently, efforts are made to increase its frequency by systematically arranging for positive, satisfying, and therefore rewarding events to occur each and every time that the response is made. Thus, for example, Bachrach et al. successfully reinstated the habit of eating in a woman suffering from anorexia nervosa, whose weight had fallen from 118 to 47 lb., by means of this technique. To do so, they arranged conditions so that pleasurable experiences, such as visits from relatives, companionship with fellow patients, music, and watching television, were entirely contingent upon her eating. This procedure has also been used to good effect in encouraging a wide variety of more socially effective behaviors in hospitalized schizophrenics. Other workers have reported successes in reinstating talking in mute catatonics and in facilitating the development of socially-oriented behavior in autistic children. Frequently, the reward of food and candy has been the successful reinforcing condition in producing such modifications in psychotic and schizophrenic patients. The technique of approximation, or shaping, constitutes an important component of this procedure. Often the desired response pattern does not appear initially in its final form. In that event, the therapist reinforces only those responses which move in the direction of the final performance which is the treatment objective. This technique was employed by Bachrach et al., and it has also been used by Bangs and Freidinger in the successful treatment of a case of aphonia, which required the patient to engage in graded vocal activities, increasingly similar to normal speech.

Negative reinforcement. In the foregoing procedure, efforts are made to increase the likelihood of a response by supplying a positive consequence whenever the response occurs. In this procedure, efforts are made to increase the probability of the occurrence of the response by exposing the patient to an unpleasant or aversive stimulus beforehand and then removing the stimulus directly after the appearance of the response which is sought. This technique has been used only infrequently since the therapist is required to expose the patient to noxious conditions until the desired response is forthcoming, thereby impairing his willingness to continue to undergo treatment. Although it has not been formally identified as such, it may, however, be a procedure which is already

being implicitly employed in such settings as prisons and reform schools.

Aversive conditioning (punishment). In arranging for conditions to occur after the emission of a response in order to reduce the likelihood of its recurrence, one of the basic procedures employed by the layman is to expose the subject to unpleasant consequences. In everyday parlance, this is referred to as punishment, but the term is rarely used in the clinical setting, for obvious reasons. However, it is a procedure which was introduced some years ago by Mowrer for the treatment of enuresis, with good effect. More specifically, conditions were arranged so that wetting the bed led to the triggering of an electric mechanism, the ringing of a bell, and the subsequent awakening of the subject. Jones, in reviewing 15 studies on this technique, discovered a recovery rate of 76 per cent among the patients treated. It has also been employed in the treatment of speech disorders by arranging, for example, for a brief blast of loud noise to follow each stuttered word. Electric shock has been applied in the treatment of occupational cramps, primarily writer's cramp, with good effect. Occasionally, verbal measures have been utilized as well. Wolpe reported that he was able to remove a patient's obsession by shouting "Stop!" whenever the patient signaled that he was experiencing an obsessive thought.

One of the reasons simple punishment has not been used more extensively stems from laboratory observations which have indicated that it is not as effective as positive reinforcement and that its primary effect has been to prompt the subject to "do something else." As a result, it has been used more often in combination with positive reinforcement, with the therapist arranging not only for the punishment of the undesired response, but also for the reinforcement of the response being sought. Thus, Walton and Black have reported the cure of an aphonic woman by manipulating the length of the practice sessions she was required to attend to reward increases in voice volume and punish volume decreases.

Extinction technique. Frequently, it is possible to reduce the likelihood that a response will occur, not so much by subjecting the patient to deleterious consequences, but by arranging for no consequences to occur at all. This is particularly useful in those instances in which the undesired response has characteristically produced some "benefit" to the patient. Thus, Walton reported the cure of a woman whose excessive scratching aggravated a severe skin rash by instructing her fiancé and family to omit the excessive attention which seemed to reinforce this response.

As is true of aversive conditioning (i.e., punishment), extinction procedures have often been used in combination with reinforcement, in the hope that this will further facilitate learning. To illustrate, this

combined procedure was applied recently in the treatment of the maladaptive classroom behavior of two psychiatric in-patients. In this case, the teacher withheld her attention from the boys until appropriate behavior occurred and then rewarded them generously with attention and encouragement. This procedure resulted in marked academic and social improvement in each of the boys.

Negative practice technique. One final procedure has been employed widely in the treatment of a variety of behaviors since its introduction by Dunlap as early as 1932. In this instance, the subject is instructed to practice the undesired response, deliberately and repeatedly. Obviously, this procedure could not be utilized in certain kinds of behavior, but it has been used with repeated success in the treatment of tics, nail biting and thumb sucking. Certain types of stuttering problems appear to respond to this approach as well. There is a great deal of disagreement as to precisely why this technique works at all, and in what way it might be related to the procedures earlier described. It is possible, however, that stable relationships between the stimuli and the response are interrupted because the response is being deliberately emitted under all sorts of stimulus conditions. It is also possible that repetition of the response produces a negative consequence (fatigue, for example), which, in turn, reduces the likelihood of its recurrence.

Applications of Behavior Therapy

As evident from the examples cited, behavior therapy techniques have been applied to a wide variety of clinical problems, in both neurotic and psychotic patients. Consistent with the approach, the treatment has focused on specific sets of problems or habits, thus giving rise to the impression that it is a monosymptomatic type of treatment. In fact, the initial efforts of behavior therapists follow the experimental tradition, in that they involve the modification of simple types of problems before attempting to alter complex combinations of disordered behavior, such as are encountered in the advanced and crystallized psychiatric syndrome. However, there is no reason why these techniques cannot be applied to complex organizations of disorder. The only prerequisite for such procedures would be the careful specification of the sequence in which the particular modifications would have to occur.

Apart from such considerations, behavior therapy may also be of particular value in the treatment of children. For one, the problem behavior manifested by these patients have not yet had time to form complex organizations and patterns. Secondly, while traditional psychotherapies may encounter real difficulties in the treatment of children because of their limited verbal facility, behavior therapy can circumvent such difficulties.

Evaluation of Behavior Therapy

Behavior therapy has enjoyed a prompt and interested response throughout the clinical field in the short time it has been in existence. Dollard and Miller's pioneering attempt to describe psychotherapy in terms of Hullian learning theory did much to create a receptive climate for behavior therapy in the United States. In the years since, many clinical investigators have adopted the approach and are submitting it to trial in a variety of contexts and in a wide array of clinical problems. An extensive literature has been accumulating rapidly. However, despite these developments, the approach is relatively new and is still undergoing modification and elaboration. A solid foundation of traditional treatment procedures has not been established as yet. No formal training centers are in existence to date, although several are in the planning stage. Most present day behavior therapists have not been formally trained but have acquired their skill as a consequence of their own initiative and experimentation.

Specific advantages. As an approach, behavior therapy appears to offer several distinct advantages. It presents a useful alternative to traditional psychotherapy, and for certain types of problems it may prove to be more effective. Thus, it has contributed to the general development of the field by encouraging different types of treatment for different types of problems. Its problem-oriented approach is conducive to the careful accumulation of data concerning response to treatment, providing for the initial establishment of a base line against which outcome and follow-up assessments can be compared. Since it is focused upon specific and limited objectives, it may require a shorter number of treatment sessions to accomplish the same result and thereby provide considerable savings in the time and expense customarily involved in treatment. It maintains a potential applicability to a wide segment of the population, as opposed to the traditional psychotherapies which have often seemed to be more suitable for persons in the higher socioeconomic brackets. In contrast, in principle, behavior therapy can be adapted to meet the needs of those who are intellectually, emotionally, or culturally disadvantaged.

Finally, and perhaps most importantly, behavior therapy provides a rationale whereby individuals other than the therapist can be trained to implement therapeutic procedures, so that parents, marriage partners, and ward attendants can function as auxiliary therapists. It may be speculated that this not only extends the range of the therapist's effectiveness but may influence the development of preventive techniques.

Effectiveness of treatment. The recovery rates reported for behavior therapy procedures are, typically, impressively high. Wolpe, for example, reports that 90 per cent of the patients treated by such procedures are cured or much improved, and this figure is im-

pressive when compared with the usual 65 to 75 per cent usually cited for short term insight therapies and the proportions below 50 per cent which have been reported for psychoanalysis. However, it must be remembered that these reports are based on subjective judgment, that such reports characteristically suffer from poor criteria for assessing behavioral change, and that better experimental controls are needed. Nor have these reports established which learning theory has proven most helpful. Certainly, no current concept of learning can be considered to be entirely satisfactory, and it is possible—indeed probable—that quite new theories will have to be developed.

Satisfactory empirical comparisons of the results of behavior therapy techniques, as opposed to other kinds of treatment, and as opposed to no treatment at all, have yet to appear. Very few such comparisons have been done so far. In one such study, desensitization procedure was compared with a traditional conversational psychotherapy and an attention-placebo treatment for alleviating "stage fright." It was reported that all three forms of treatment had some effect, although the traditional counseling was not more effective than the placebo, while systematic desensitization was significantly more beneficial than either of the other two techniques. On the other hand, in a carefully controlled study by Cooper, two groups of patients, one of which had been treated by behavior therapy and the other by a variety of other methods available in the Maudsley Hospital, were followed up a year later. In this instance little if any difference was found between the two groups.

Conclusions

Despite the enthusiastic emphasis upon a new and different approach to the treatment of behavior disorders which characterizes the writings of many behavior therapists, it is possible to demonstrate that there is no basic incompatibility between the more traditional psychotherapeutic approach and behavior therapy (Peterson and London), that many of the procedures employed in behavior therapy have also been employed in the context of the verbal psychotherapeutic methods (Ford and Urban), and that many of the principles underlying the implementation of each may be the same. Finally, careful study of behavior therapies reveals that they do, in fact, deal with both subjective responses (personality) and overt responses (behavior).

Even so, the emphases within behavior therapy will prove to be extremely useful to the field as a whole. Despite the fact that traditional psychotherapy has dealt with many of the same issues and techniques, the scales may have become tipped in the direction of an overemphasis upon the subjective antecedents of behavior, with a corresponding neglect of objectively observable aspects of behavior and its dependence upon situational determinants. Behavior therapy will

provide a useful service in helping to redress the balance. Finally, its greatest strength lies in its basic goal—to establish clinical technique firmly upon the foundation of the basic experimental disciplines. Nothing could be more useful than the reminder that the knowledge and methods of the laboratory scientist can be successfully applied in the clinical situation, as illustrated by the fact that treatment procedures can be derived from learning theory, explored in the laboratory, and subjected to controlled clinical tests.

Suggested Cross References

The various learning theories from which behavior therapy derives are discussed in Area B of this volume (see Chapter 3, on basic psychological sciences). See also Area C for a more detailed discussion of current theories of personality and psychopathology and the other sections in this chapter for alternate viewpoints of psychotherapy. For a discussion of the issues regarding symptom removal as opposed to treatment of the underlying disorder, see Frazier and Carr's section (Section 23.4) on the phobic reaction in Area F, on psychiatric disorders.

34.3 CLIENT-CENTERED PSYCHOTHERAPY

CARL R. ROGERS, Ph.D.

History

Client-centered psychotherapy was conceived of and came to fruition in the period from 1938 through 1950: it underwent its initial development at Ohio State University in the years from 1940 through 1945; during the following 5-year period, from 1945 through 1950, it was further elaborated at the Counseling Center at the University of Chicago.

The label "client-centered psychotherapy" was intended to underscore a focus on the internal phenomenological world of the client, or patient. The term "client" was chosen to indicate that the individual seeking help is perceived (and valued) as a self-responsible person, rather than an object for treatment. Initially, these clients consisted primarily of maladjusted and neurotic students, children, and parents; however, in the years since, the patient population has expanded to include a continuum ranging from chronic schizophrenic patients to competent business executives seeking self-enhancement.

From the beginning, client-centered psychotherapy has been noted for its dynamic quality: it does not represent a dogmatic school of thought but has changed over time, as a result of the knowledge gained through the increasing and varied experience of the large group of therapists using this approach. Other changes have emerged from the findings of a continuing, multifaceted program of research.

Distinctive Characteristics of Client-Centered Psychotherapy

Since it is obviously impossible to touch on all the aspects of the client-centered approach in this very brief exposition, it might be well at the outset to state a number of the characteristics which distinguish this point of view from other forms of psychotherapy. Of these, some characteristics can only be cited; others will be described briefly. These distinctive elements include: (1) the developing hypothesis that certain attitudes in the therapist constitute the necessary and sufficient conditions of therapeutic effectiveness; (2) the developing concept of the therapist's function as that of being immediately present and accessible to his client and relying on his moment-to-moment experiencing in the relationship with the client; (3) the continuing focus on the phenomenal world of the client; (4) a developing theory that the therapeutic process is marked by a change in the client's manner of experiencing, with increasing ability to live more fully in the immediate moment; (5) continued stress on the self-actualizing quality of

the human organism as the motivational force in therapy; (6) a concern with the process of personality change, rather than the structure of personality; (7) emphasis on the need for continued research to gain essential truths regarding psychotherapy; (8) the hypothesis that the same principles of psychotherapy apply to all persons whether they are categorized as psychotic, neurotic, or "normal"; (9) a view of psychotherapy as one specialized example of all constructive interpersonal relationships, with the consequent generalized applicability of all knowledge gained from the field of psychotherapy; and, (10) a concern with the philosophical issues which derive from the practice of psychotherapy.

The Developing Concept of the Therapeutic Relationship

Concurrent with the development of client-centered psychotherapy, there has gradually evolved the concept that therapeutic success is dependent not primarily on the technical training or skills of the therapist, but on the presence of certain attitudes in the therapist. When they are effectively communicated to and perceived by the client, these attitudes are considered to be the crucial determinants of therapeutic progress and constructive changes in personality. Concomitantly, it is hypothesized that it is these attitude patterns which account for change, whether one is dealing with "normal," neurotic, or psychotic individuals. Thus, the client-centered point of view represents a unified approach to therapy, no matter what diagnostic label has been assigned to the client, or patient. In this respect, the client-centered approach differs sharply from other therapeutic orientations.

Therapist's attitudes. Three attitudes or conditions appear to be most important for the success of therapy, on the basis of research findings. These are: (1) the therapist's genuineness, or congruence; (2) the therapist's complete acceptance, or unconditional positive regard for his client; and (3) a sensitive and accurately empathic understanding of the client by the therapist.

Genuineness of the therapist. The presence of this attitude, which is perhaps the most basic, means that the therapist is endeavoring to be what he is during his encounter with his client. He is without pretense, openly reflecting the feelings and attitudes which he is experiencing at the moment. Obviously, this requires self-awareness on the part of the therapist. The feelings he is experiencing must be available to him, so that he may deal with these feelings and communicate them if they persist. It also means that the therapist enters into a direct personal encounter with his client, meeting him on a person-to-person basis. It means that he is *being* himself, not denying himself.

Since this concept is liable to misunderstanding, it may be advisable to state some of the things this atti-

tude does not imply. It does not imply that the therapist will burden his client with the overt expression of *all* his feelings. Nor does it mean that the therapist must disclose his total self to his client. It does mean, however, that he will not deny to himself the feelings he is experiencing at the moment—that he is willing to acknowledge any *persistent* feelings, negative or positive, which exist within him in the relationship, and to communicate these to his client. It means he will avoid the temptation to adopt a facade, to hide behind a mask of professionalism, or to adopt a confectional-professional attitude.

The second and third attitudes which are described in the following paragraphs also facilitate therapy, but if the therapist is genuine in the relationship with the client, he may be helpful even when he is not experiencing these other attitudes.

The therapist's unconditional positive regard for the client. The presence of this second condition which appears important for therapeutic movement and change means that the therapist communicates to his client a deep and genuine regard for him as a person with potentialities, a regard which is uncontaminated by evaluations of his thoughts, feelings, or behavior. The therapist experiences a warm acceptance of the client's expressions as part of his total personality and places no conditions on that acceptance and warmth. He does not accept certain feelings in his client and disapprove of others. Rather, this condition implies *not* making judgments. It implies that the client's expressions of painful, hostile, defensive, or abnormal feelings will receive as much acceptance as his expressions of good, positive, and mature feelings.

Unconditional positive regard, when communicated by the therapist, functions to provide the nonthreatening context in which it is possible for the client to explore and experience the most deeply shrouded elements of his inner self. The therapist is neither paternalistic, nor sentimental, nor superficially sociable and agreeable. But the fact that the therapist really cares about the client is a necessary ingredient in his efforts to create a "safe" environment in which the client will be motivated to explore his deepest thoughts and feelings and share them with another human being.

Accurate empathic understanding. The third essential attitude for a productive therapeutic relationship is empathy. It implies that the therapist is completely at home in the universe of the client. It is a moment-to-moment sensitivity to events in the immediate present. It is the therapist's ability to sense and understand the client's inner world of private personal meanings, as if it were the therapist's own, but without loss of the "as if" quality.

The ability and sensitivity required in order for the therapist to communicate his understanding of these inner meanings to the client in a way that allows these experiences to be "his," is the other major aspect of accurate empathic understanding. The

therapist's ability to sense the client's fear, his confusion, his anger or rage, as if these were feelings the therapist himself might possess (but is not currently experiencing) is the essence of the perceptive aspect of accurate empathy. Communicating this perception in a language attuned to the client, and thereby allowing him to sense and formulate his fear, confusion, rage, or anger more clearly, is the essence of the communicative aspect of accurate empathy.

Validation of the therapeutic importance of these attitudes. Research investigations have tended to confirm the hypothesis that these three attitudes are important antecedents of therapeutic movement and progress. This statement is applicable both to neurotic individuals who are strongly motivated to seek help and to chronic schizophrenic persons with no conscious desire for help. It applies whether these attitudes are rated by impartial investigators, after they have listened to segments of recorded interviews, or whether they are measured by the Relationship Inventory, which taps the client's own perception of the therapeutic relationship. It has also been found that these attitudes remain quite constant throughout therapy, so that the degree to which they are present as early as the fifth interview constitutes a good prediction of the degree of objectively measured change which will take place in the client. Thus, the ultimate success or failure of treatment can be predicted with a modest degree of accuracy at a relatively early stage.

The Therapeutic Process

It is impossible, of course, to do justice to the richness of the therapeutic process in this brief account. In a broad sense, the process may be described as the client's reciprocation of the therapist's attitudes. As he finds someone listening to him with consistent acceptance while he expresses his thoughts and feelings, the client, little by little, becomes increasingly able to listen to communications from within himself; he becomes able to realize that he is angry, or that he is frightened, or that he is experiencing feelings of love. Gradually, he becomes able to listen to feelings within himself which have previously seemed so bizarre, so terrible, or so disorganizing that they had been shut off completely from conscious awareness. As he reveals these hidden and "awful" aspects of himself, he finds that the therapist's regard for him remains unshaken. And, slowly, he moves toward adopting this same attitude toward himself, toward accepting himself as he is, and thus prepares to move forward in the process of becoming. Finally, as the client is able to listen to more of himself, he moves toward greater congruence, toward expressing all of himself more openly. He is, at last, free to change and grow in the directions which are natural to the maturing human organism.

Theoretical model. A more technical description of the therapeutic process, which is supported by empirical findings is appropriate here.

It is established knowledge that the client in the process of therapy shows movement on each of a number of continua. Starting from wherever he may be on each continuum, he moves toward the upper end. Regarding feelings and personal meanings, the client moves away from a state in which they are unrecognized, unacknowledged, and unexpressed; he moves toward a flow in which continually changing feelings are experienced in the moment, knowingly and with acceptance, and may be accurately expressed.

This process involves a change in the manner of the client's experiencing. Initially, he is remote from his experiencing. For example, the person who intellectualizes talks about himself and his feelings in abstract terms, leaving the therapist with serious doubts as to what is actually going on inside him. From this position of remoteness, he moves toward an immediacy of experiencing, in which he lives openly in his feelings and knows that he can turn to his experiencing to discover its current meaning. The process involves a loosening of the cognitive maps of experience. Whereas he previously construed experience in rigid ways which were perceived as external facts, the client now moves toward having changing, loosely held constructions of meaning in experience, constructs which are modifiable by each new experience.

Results of Client-Centered Therapy

Data from a wide variety of research studies suggest that individuals who are involved in the type of relationship just described, even for a relatively limited number of hours, show profound and significant changes in personality, attitudes, and behavior, changes that do not occur in matched control groups. Even though it may be imperfectly realized, in this type of therapeutic relationship the individual becomes more integrated, as evidenced by projective tests, for example. He shows fewer of the characteristics which are usually termed "neurotic" or "psychotic," and more of the characteristics of the healthy, well functioning person. He alters his perception of himself, his self-concept becomes more realistic, and he becomes more like the person he wishes to be. He values himself more highly, and he has a greater capacity for self-direction and self-expression. He achieves greater self-understanding; becomes more open to his experience, denying or repressing less of it; becomes more accepting in his attitudes toward others, seeing others as more like himself. In his behavior, he shows similar changes. He is less frustrated by stress and recovers from stress more quickly. His day-to-day behavior becomes more mature. He is less defensive, more adaptive, better able to cope with difficult situations and problems.

Continuing expansion of research. One of the distinctive features of client-centered therapy is that from the beginning it has been focused upon research. As an approach, it has been committed to the belief that the phenomena of therapy may, and should, be

subjected to rigorous research investigation. To this end, thousands of therapeutic interviews have been electrically recorded and have provided the raw data for many studies. Live interviews have been filmed as well, in order to subject the process to a closer, even more intensive, investigation. An annotated bibliography (Cartwright, 1957) showed that the reports of more than 100 investigations had been published on all phases of therapy—the therapeutic relationship, the process, the results, and the theoretical formulations and predictions.

Since the publication of that bibliography, there has been an increase in the development of research in all its phases. New instruments have been devised for the measurement of therapeutic conditions. Various scales have been prepared for assessing the effectiveness of the therapeutic process. A research project to investigate the efficacy of psychotherapy with hospitalized schizophrenics has been completed. An exhaustive study of time-limited therapy has been conducted. Many individual research projects, investigating different aspects of client-centered psychotherapy, or investigating hypotheses growing out of the theory on which it is based, have been completed.

Applications of a Client-Centered Approach

In client-centered therapy the therapeutic relationship has always been conceived of as a special instance of interpersonal relationships in general. Change and growth in therapy has also been seen as a special instance of growth and development in any human being. Perhaps it is because of these two points of view that client-centered theories and methods have been utilized in a wide variety of settings which bear no resemblance to the formal therapy situation. The client-centered approach has had a wide and receptive audience, not only among therapists, but among school and vocational counselors, leaders in the field of group dynamics, marriage counselors, industrial counselors, speech therapists, teachers, business executives, clergymen of many faiths, social case workers, and others. And it has been used effectively in widely different cultural settings—in France, Belgium, Italy, and Japan, for example. Workers in community development in this country and in other countries have drawn upon client-centered theory and practice to facilitate the independent growth of community responsibility and problem-solving skill. In brief, this point of view has been perceived as having significance for many people in varied occupations and diverse cultures.

Hypnotic phenomena have probably occurred in one form or another since the beginning of man. However, these phenomena were first mentioned as a therapeutic tool in the 18th century by Mesmer, who referred to hypnosis as "animal magnetism." In the next century, Braid, Charcot, Liebeault, Bernheim, Janet, Freud, and many others studied hypnotic phenomena. Since the early 1930's, there has been a resurgence of interest in the medical uses of hypnosis in the United States, which has been pioneered and influenced largely by M. H. Erickson.

Our knowledge of hypnosis has evolved in much the same way as our knowledge of transference, which appears to be a basic element of hypnosis. When the concept of transference was first introduced in psychoanalysis, many psychoanalysts erroneously assumed that the phenomenon occurred only in the analyst's office and in relation to the analyst. However, when the concept of transference was further developed and clarified as referring to that aspect of the patient-doctor relationship which is nonrational, it became apparent that transference occurs more or less frequently, if not constantly, in varying degrees of intensity with different people. It also became evident that the clinician can identify transference phenomena by scrutinizing both the patient's perceptions and his evaluations of them.

By the very nature of the patient-doctor communication in the psychotherapeutic setting, the documentation of transference phenomena, as they occur in that relationship, is likely to be greater than our knowledge of the phenomena which underlie any of the patient's other associations. But there is no reason to believe that the transference phenomena observed in psychotherapy are not representative of what goes on regularly, probably even more intensively, in many other facets of the patient's life.

The individual's ability to achieve a hypnotic trance, that is, to become more or less fixed or "frozen" in a dissociated state, is probably activated and reactivated many times during his lifetime. If the clinician can help the patient to experience this hypnotic state of dissociated concentration and, at the same time, structure it toward the therapeutic goal, conditions are favorable for using hypnosis as an adjunct in treatment.

For centuries, poets, writers, and philosophers, as well as clinicians and scientists, have alluded to the many levels of awareness experienced by human beings from day to day, and even from moment to moment. But when the clinician structures and maintains a specific type of dissociation in the patient, we can, by definition, call this "hypnosis." The crucial difference between this state of hypnosis and other dissociated states the same patient may experience is that the patient is responding to a stimulus which has been knowingly established and perpetuated by the clinician according to a deliberate design, and in order to achieve a specific goal.

34.4 HYPNOSIS: AN ADJUNCT TO PSYCHOTHERAPY

HERBERT SPIEGEL, M.D.

Nothing can be done in psychotherapy with hypnosis that cannot also be done without hypnosis. The advantage of hypnosis lies in the fact that it serves to accelerate, sometimes considerably, the impact of psychotherapeutic intervention.

If it is true that hypnotic phenomena occur spontaneously, as seems evident, the physician can expand his clinical skills by learning to identify trance capacity and then to activate, control, and channel it for defined therapeutic goals.

A heuristic view. The definition of the word "hypnosis" (from the Greek word *hypnos*, meaning sleep) can be misleading because the phenomenon to which it refers is not a form of sleep; rather, it is a complex process of heightened or aroused concentration. Although peripheral awareness is reduced in sleep and hypnosis alike, focal awareness, which is almost obliterated in sleep, is at optimal capacity in hypnosis.

It is difficult to estimate the number of instances when dissociation occurs without the "official" label of hypnosis. For example, women who deliver their babies by means of muscle relaxation techniques without chemical anesthesia are experiencing the equivalent of hypnoanesthesia, although neither the doctor nor the patient may acknowledge that hypnosis is being used. Similar experiences occur among patients who endure such procedures as direct laryngoscopic, gastroscopic, and proctoscopic examinations without awareness of pain or discomfort. When a drug has a so-called placebo effect, this may be interpreted as indicating that various dissociated experiences occur in the therapeutic setting that are beyond the direct effects of the drug itself. Outside the clinical setting, variants of the complex phenomenon of dissociation called hypnosis are experienced in fugue states, sleepwalking, day-dreaming, intense concentration on work or play, and "miracle" cures.

Characteristics of Hypnosis

There are a number of theories which attempt to describe the essential nature of hypnosis. Their mere abundance is, in itself, evidence of the difficulty of formulating a concept of the phenomenon in terms of its elements. However, an operational, phenomenological definition is possible.

Definition. Hypnosis can be described as an altered state of intense and sensitive interpersonal relatedness between hypnotist and patient, characterized by the patient's nonrational submission and relative abandonment of executive control to a more or less regressed, dissociated state. In the clinical situation, it is actively instigated and knowingly enhanced by the hypnotist and structured for goal achievement.

Hypnosis is a structured form of aroused concentration that can be disciplined and directed toward specific therapeutic goals. In practice, the operator provides one of the signals that activates the patient's capacity for a shift in attention to guided areas. The patient's dissociated attention is constantly sensitive to, and also responsive to, cues from the hypnotist, thereby permitting the patient to concentrate intensively on areas or conditions the clarification of which can lead toward the designated goals.

Capacity for hypnosis. It should be emphasized that the patient must have a latent capacity for aroused concentration which can be tapped and then structured by the hypnotist-therapist. The notion, based on the Svengali-Trilby myth, that the hypnotist can project or exert some mysterious power on the subject, has never been substantiated clinically or experimentally. The most that a hypnotist can do is provide an appropriate occasion for the subject to activate his own capacity for the trance experience. This capacity, or lack of it, is not necessarily identified by the patient's conscious evaluation of his hypnotizability. Some patients who assert that they urgently want hypnosis are incapable of entering the

trance state. Others may openly defy the trance-inducing signals and simultaneously enter the trance.

The three phases of trance induction. The phenomenon of trance induction is a three-stage operation, although the delineation of each is not always discrete.

Patient's perception of the aura. This is an anticipatory phase, which is anxiety-provoking to the extent that it elicits whatever transference potential exists in the patient. If the reputation of the hypnotist, his appearance, or his presentation is such that it coincides with the patient's transference predisposition or expectancy, the necessary rapport is comparatively easy to establish. The patient thus becomes more receptive to the physician's signals to enter the trance; he is apt to reach a more intense dissociation and is therefore able to accept more fully the directions given him during the trance state.

Psychophysiological enhancement. During this second phase, the art of induction consists of (1) the hypnotist's indicating, in advance, the probable, and therefore the predictable, psychophysiological phenomena that will occur when the patient takes the position and performs the physical acts according to his directions, and (2) the hypnotist's tacit implication that these phenomena are due to his signals. In addition, the patient's suspense, resulting from his repetition of the specified movements and the passing of time, accentuates the psychophysiological effect.

The "plunge." During the third phase of trance induction, the patient more or less abandons his executive controls and shows nonrational submission to a dissociated state. The situation is analogous to that of the swimming coach and the swimmer. The coach can guide the swimmer to the edge of the pool, can instruct him how to jump into the water, and can even anticipate his actions once he has jumped. But at some point the swimmer's tie with the coach cannot determine the ease, speed, and confidence with which he explores the water. Similarly, the hypnotist has the broad power to structure the nature of the patient's nonrational plunge into submission with relative abandonment of his executive control. However, he cannot determine either the moment or the manner of the patient's submission.

The specific induction technique is almost inconsequential in the production of the trance. Creating an atmosphere of appropriate security and relaxation is important. But these elements are secondary, compared to the expectation of both the patient and the doctor and the relationship between them. The patient is encouraged to make himself comfortable and to concentrate. The operator may then ask him to gaze at a dot on a card, a spot on the ceiling, or a pencil point; to roll his eyes up, as if he were trying to look at his eyebrows; to concentrate on holding one hand in a raised position; to sway back and forth from a standing position until he falls back into a chair placed behind him; or to perform any one of an

almost limitless number of procedures that involve concentration. In brief, the operator chooses a technique with which he feels comfortable and confident, and which the patient finds acceptable (and sometimes even expects).

The phenomenology. The specific objective and subjective phenomena which occur can vary widely, depending on the expectations of the subject and the hypnotist. Allowing for this, in Western culture, the trance state can generally be characterized for practical clinical purposes as existing at one of three levels. The light trance is most readily identified by motor alterations, e.g., hyperkinesis or retardation. The middle range is usually distinguished by these changes, plus sensory alterations, such as paresthesia, analgesia, anesthesia, partial amnesia, and posthypnotic compliance to simple signals. The deep somnambulistic level is characterized by the additional features of posthypnotic compliance even to bizarre signals; visual, auditory, and tactile hallucinations; time distortion; age regression; hypermnnesia or selective amnesia; profound anesthesia; and the ability to maintain the trance state with the eyes open.

These levels are by no means fixed; they may vary in the same subject from time to time, and even within the same trance experience. However, when the operator's instructions are appropriate, the level generally tends to remain fairly constant and to be responsive to the conditions necessary to achieve the desired treatment goal as understood by the patient. For example, a woman who has successfully delivered her baby by hypnosis without chemical anesthesia has attained her goal. Since she no longer needs to concentrate on being aware of her sensations, she may ask for chemical anesthesia while the episiotomy is being repaired.

Compulsive triad. Of all the phenomena related to hypnosis, none is more impressive than the patient's post-trance compliance to an instruction given him during the trance. To illustrate, while the patient is in a deep trance, the hypnotist tells him that when he is out of the trance, he will respond to a specified signal in a specified way. Moreover, he will respond in the predictable pattern that prevails in all such post-trance responses. For example, while hypnotized, a patient may be told that when the hypnotist lights a cigarette after the trance, the patient will ask for one, puff at it once or twice, and then put it out. It can be predicted with confidence that after the trance the patient will do precisely this. It is also predictable that (1) he will have an amnesia (more or less) to the general context of the instruction (technically called the signal), (2) he will comply with the instruction compulsively, and (3) he will rationalize his act of snuffing out the cigarette by saying, "This cigarette is stale," or "I must be catching a cold," or something along those lines.

These three reactions, which are identified as a "compulsive triad," constitute a potent, identifiable

constellation of predictable behavior. The triad can be regarded as a unit of organized behavior that is at least partially dissociated and, at the same time, predictably responsive to a preconditioned stimulus. Moreover, while the triad is most clearly seen when the signal has been planted during a deep trance, it can also be observed in an attenuated form when the signal has been implanted during a light trance. The patient may not have total amnesia, but the compulsive compliance is subtly apparent, in that he shows mild discomfort or anxiety and seems obliged to rationalize his feelings.

The compulsive triad also appears in nonhypnotic experiences. A person may have received a certain signal in childhood, and may have given a certain response that was appropriate to his mode of life and private beliefs at that time. Years later, when a similar signal occurs, the person, motivated by the psychological compulsion to repeat and by transference, exhibits the triad of amnesia around the original stimulus, compulsiveness in repeating his original response, and rationalization of his act. Furthermore, his current response is motivated by his past conditioning; it does not represent a rational reaction to his present situation.

In the compulsive triad the psychiatrist has available a unit of predictable behavior that he may use therapeutically. For example, he can study the role of this behavior unit in the patient's development, or he may use it to influence or to inactivate certain behavior. As these behavior patterns emerge, he learns more about the patient's specific assumptions about himself and the world around him. By induction, the therapist gains knowledge that can contribute to his evaluation of the patient.

Psychotherapeutic Application of Hypnosis

The major function of the doctor who uses hypnosis in psychotherapy is to design a sound psychotherapeutic program which aims at solving the patient's problems. Almost any of the treatment designs discussed elsewhere in this chapter may serve as the appropriate primary treatment strategy. Hypnosis is not a treatment in itself, but an adjunct to treatment. It enables the psychiatrist to focus the patient's intense concentration on certain areas. The desired information can be reached more directly through hypnosis than when the psychiatrist must depend on the patient's free association, with its mass of resistances, irrelevant information, and conscious censure. Since the patient's intensified transference and attention are focused on the treatment situation, an atmosphere of receptivity enhances his capacity for exploration and change. But the clinician's ability to hypnotize a patient does not, in itself, assure therapeutic success. This will also depend on the physician's knowledge and skills in helping the patient to move toward relevant therapeutic goals.

Prerequisites for therapeutic effectiveness

Therapist's role. If the therapist believes that the dissociation and concentration obtained in hypnosis can facilitate treatment, he must assume certain responsibilities. In general, these may be formulated as follows. (1) The therapist must identify the capacity of the patient for the trance experience. This is determined by a brief trial with one of the many induction techniques and will depend on the psychiatric evaluation as well. Approximately four out of every five persons are capable of at least a light trance. In fact, even psychotic patients have periods of lucidity during which they may be capable of the concentration necessary for hypnosis. (2) The therapist must provide the optimal conditions necessary for the trance, including patient-doctor rapport, security, and physical comfort. (3) The trance must be structured in accordance with the therapeutic goals; the therapist is obliged, therefore, to delineate these goals in terms of the patient's needs and ascertain that they are clearly understood by the patient. (Naturally, the therapist must also have the skills necessary to induce and maintain the trance, and be able to handle the material produced in the trance state.) (4) Finally, the therapist must educate the patient to respond at a given signal in the service of the treatment program. Moreover, in some instances, the patient must be taught to produce this response in his daily life, as well as in the clinical setting.

Patient orientation. The adjunctive role of hypnosis lies in its ability to reduce the time needed for treatment by cutting through the patient's resistance, thereby permitting the therapist to use transference as a therapeutic device, operative in a desirable direction. As in all psychotherapeutic encounters, the effectiveness of hypnosis will depend on the patient's well-being, which, in turn, will be determined by the following conditions: (1) restoration of the patient's previous level of self-esteem; (2) the alleviation of stress in his environment; (3) the patient's reformulation of the symbolism of his symptom into a less extreme form (although the basic language will remain the same); and (4) the provision of a clinical atmosphere of flux which will allow the patient to re-order his own evaluation of the complex balance between the possible secondary gains derived from invalidism and the loss of his self-respect as a result of the same invalidism. Failure to achieve this critical reorientation can sabotage the ultimate treatment goals and any meaningful consolidation of change toward health, even when symptoms are demonstrably revoked in the treatment setting.

Basic Strategies in the Use of Hypnosis

The use of hypnosis to facilitate psychotherapy involves two basic strategies: the first strategy is to enhance the patient's control; the second is to uncover the material the patient has repressed. These two

motifs are not mutually exclusive and may be used with the same patient during different phases of treatment. Usually, however, one strategy tends to dominate the type of treatment application in any given therapeutic project.

Control enhancement. Control enhancement is usually focused upon (1) symptom alteration, or (2) attitude alteration, as substitutive and diversionary experiences. These are essentially suppressive and containment operations, designed to increase the patient's control so that he can learn more effective ways of achieving the defined goals of his therapy. The techniques may overlap, and sometimes they are used at the same time. Apart from such considerations, in general, the safe and appropriate use of symptom and attitude alteration requires only the knowledge of human behavior which is expected of any competent clinician.

Symptom alteration. Symptom alteration is simply direct guidance which veers the patient's attention away from his symptoms and concomitantly reminds him that more resourceful and effective means are available for his use in coping with problems of adaptation. For example, an embarrassing exposed head tic may be converted to a hidden toe tic, and panic may be converted into problem-solving. The phobic reactor can learn to differentiate real danger from generalized fear, and a confused, disoriented person can reestablish time, place, and self-identity.

Attitude alteration. Attitude alteration presents the patient with an alternative attitude toward a chronic, recurrent disability or a pending problem-posing event; and, by invoking the power of compulsive compliance with the posthypnotic signal, it influences the patient to abandon old perspectives and adopt new ones in the service of more effective adaptation. For example, compulsive cigarette smoking can be stopped when the patient concentrates on his new need to respect his body and to protect it from poison; pain can be endured when a mother wants to experience the birth process and to deliver her baby without chemical anesthesia; psychogenic paralysis can be cured when the patient realizes that he no longer has the need for invalidism; phonation can return when the aphonic patient learns a new way to express and cope with a secret, critical grievance; depression can lift when confusion about guilt is clarified.

Uncovering repressed material. Uncovering that which is repressed, both affective and cognitive content, may be accomplished (1) by simple abreaction, or (2) by more complex exploration of past events.

Abreaction. The release of repressed material can sometimes be provoked by design. Frequently, however, such material bursts through without an evocative signal from the therapist when the appropriate therapeutic atmosphere has been established. The sanctioned abandonment of the patient's executive control to the therapist may be sufficient to permit the release of highly charged affect. This occurs fre-

quently in attenuated form during the course of the patient's various psychotherapeutic experiences. However, it is usually in patients whose syndromes developed as a result of recent situational catastrophic experiences, such as war, fire, or accident—experiences which, if not uncovered, may develop into traumatic neuroses. Often, just the opportunity for release provided by the treatment setting and the subsequent reconstitution of self-esteem are all that are needed for clinical success. For example, the battle casualty can reenact the traumatic event, recall forgotten details, give vent to his fears and guilt, and discover that he can still live with honor.

Explorative uncovering. This is the most subtle form of hypnotic intervention in psychotherapy. It makes use of the hypermnnesia that is possible in this state of aroused concentration, and it permits a piecemeal collection of presumably isolated data from the past. To illustrate, a remembered episode of being choked reawakens old attitudes toward an older brother. When the connections and trends become apparent, an insight is permitted that frees the patient sufficiently to change toward health. This process is sometimes called hypnoanalysis; this is a misleading term, however. First, in this context, hypnosis is not primary but secondary to the explorative technique. Second, this is not analysis in a psychoanalytic sense. The therapist is maneuvering so actively in the role of hypnotist that he cannot observe the many transference and countertransference phenomena as readily as the analyst can in the usual psychoanalytic interchange. In intensive psychotherapy, without the strictures of the psychoanalytic technique, however, the explorative uncovering can be a valuable data-collecting procedure, especially when amnesia for specific events is at issue.

Precautions and Contraindications

In general, hypnosis is remarkably safe when it is used with sound clinical judgment, in a goal-directed setting. There are, nevertheless, some precautions to be observed.

Usually, the suspicious or paranoid patient will avoid or resist efforts at hypnosis and evoke a self-protective defense against this intrusion. Occasionally, however, such a patient may go into the trance state, only to have the experience evoke latent fears and suspicions which present a potential threat to the physical safety of the therapist. As a useful safeguard against this type of reaction, the hypnotist should pace the hypnotic intervention in accordance with the interests and desires of the patient and never use coercive ploys. This allows the patient the freedom to stop whenever he feels threatened by the interaction.

Another concern arises with respect to the sensitive, fragile patient who has already suffered many painful failures. If his expectations regarding the rewards to be derived from hypnosis are unrealistic and therefore unlikely to be fulfilled, the probable failure may be

so traumatic that the risk of disappointment is not clinically justifiable. However, with time and clarification, the patient's high expectations and the impact of disappointment may become attenuated sufficiently, so that the experiment may be attempted with reasonable safety.

Generally, a hypnotized subject cannot be coerced into performing an action that violates his values and beliefs. However, since perceptions can be temporarily altered by hypnotic signals, it is possible that, during the time period necessary to discover the disparity between the patient's compulsion to comply with the therapist's signal and his resistance to it, he may feel confused and unable to exercise his best judgment. During this transient period, the patient may commit an act which is somewhat disparate with his usual conduct. The more intense the trance state, the greater the likelihood that this can become a critical issue. It is self-evident, therefore, that the operator must assume a degree of responsibility for the patient, especially during the time period when he has entrusted some of his usual controls to the operator. In this respect, the hypnotist's responsibility toward the patient is not unlike that of the anesthetist toward the anesthetized patient.

To illustrate, a hospitalized patient was given a posthypnotic signal to fall asleep at 10:00 P.M. She did so; but at the time she was sitting in a chair watching television in the ward room, and she had to be carried to bed. The posthypnotic signal had been faulty. It should have included the qualification that the patient would respond to the signal only when she was in bed and prepared for sleep, at 10:00 P.M. or thereafter. One might speculate that, if the patient had been walking through the hospital corridors or along the street at 10:00 P.M. and, because she was unable to use her own judgment, had suddenly fallen asleep, she might have been injured. (At the same time, it is possible that under such circumstances the patient might have experienced a quick transient confusion and have fought off the signal to fall asleep until she could get into bed.)

The point should be emphasized, however, that the hypnotized patient needs supervised protection until sensory-motor alterations are corrected by customary controls.

In a broader sense, clearly, the use of hypnosis as an uncovering device demands certain precautions. The explosive abreaction may require psychological restitutive measures which are part of the repertory of the experienced psychotherapist. Therapist-induced explorations into amnesic realms of the past can become mischievous unless they are conducted in a disciplined manner within a designed treatment program. Therefore, for the protection of the patient, the uncovering and explorative applications of hypnosis should be performed only by those clinicians who are adequately trained in reconstructive psychotherapeutic techniques.

Just as hypnosis in the treatment setting can facilitate a thrust toward health, it can also facilitate a therapeutic "error." The leverage potential works both ways for the intervener. When a therapist com-

mits an error in a nonhypnotic setting, the patient who has ready access to his own faculties can critically judge and cope with the error, at least to some extent. However, this same capacity for critical appraisal is not readily available to the patient in a trance state, so that correction of the error either is delayed or may not be made at all. The existence of such a possibility lends support to the contention that, as a general rule, intensive short term insight therapy should only be practiced by the experienced psychotherapist. The novice needs the checks and balances that are possible when psychotherapy proceeds at a slower pace. Similarly, the risk of error further emphasizes the needs to limit the general use of hypnosis to symptom and attitude alteration in the service of containment and control, and to reserve the uncovering techniques for those clinicians who have been trained in the psychodynamics of intervention.

of the therapist with the patient, verbally or through limited affective demonstration; (2) the direct interpretation, in Freudian terms, of the patient's psychotic thoughts and behavior (i.e., the therapist "talks" to the patient's unconscious); and (3) the assumption by the psychiatrist of an authoritative and omnipotent, yet benevolent and accepting, "foster mother" role toward the patient. The third element is the governing principle of the method.

Concept of psychosis. This form of treatment is based on the assumption that psychosis is psychogenic and that it differs from neurotic or normal behavior mainly in degree of disturbance. The neurotic state always precedes the psychotic, and after treatment the patient reverts to a "neurosis." Every psychosis can be divided into eight phases, which vary in severity. In the Freudian idiom, these correspond to the pregenital levels of development to which the psychotic is said to regress, ranging from early oral to late anal. Basically, a psychotic person is reexperiencing a distorted infant-mother relationship (not necessarily as it existed in reality, but as the child interpreted it), which has taken the form of an inner ego-superego conflict. Because of some deviation in her "mothering instincts" (whether real or imagined), the mother is perceived as "indispensable, but deadly."

Treatment Techniques

Although few formal techniques of therapy have been specifically enunciated by Rosen, recent observers of his methods have attempted to codify several of the more familiar procedures. These have been described as follows. (1) The therapist makes transference interpretations, the nature of which depends on the phase of the psychosis, in which he is referred to as the omnipotent figure. (2) Direct interpretations are made, more in keeping with the manifest content of the patient's productions, which contain no reference to the therapist. (3) The transference is focused, the internalized, "bad" mother is then attacked, and the therapist is substituted as the "good" mother figure. (4) The therapist enters into the psychosis, and therapist and patient are allied against the patient's illness ("insanity" or "craziness"), which the patient must then accept. (5) The therapist promises to help, care for, and cure the patient. (6) Finally, there is some affective demonstration by the therapist, for instance, by seductiveness or tactile contact. Those factors and processes which are typically associated with psychotherapy, e.g., insight, dreams, abreaction, and the confidentiality of the therapeutic situation, are not considered essential in this context.

Treatment setting. Originally, the treatment was carried out in a state hospital setting; later, it was attempted in private practice. As it is practiced currently, the patient lives in a foster family-like setting with several assistants (either former psychotics or

34.5 DIRECT ANALYSIS

JACK L. RUBINS, M.D.

Introduction

Direct analysis is a unique method of psychological treatment of the psychoses—specifically, the schizophrenias, manic-depressive reactions, and paranoid states—which was promulgated by Rosen in 1943 and later refined by him. In general, treatment consists of three elements: (1) the active intervention

students) who are with him constantly and whose primary function is to administer to the patient's physical needs and reinforce the psychiatrist's interpretations and role.

Duration of treatment. Resolution of the psychosis may take from a few weeks to more than a year; on the average, the duration of treatment during the acute phase of the illness is 4 months. Follow-up treatment during the neoneurotic phase is on a weekly or biweekly basis and may last an indefinite time. During this phase, standard techniques are used, and no direct interpretations are made. Follow-up treatment is directed toward resolution of the oedipal situation; i.e., having identified with the "mother-psychiatrist," the patient must now form an adequate relationship with the "father-psychiatrist."

Evaluation of Treatment

The effectiveness of this method of therapy is still in dispute. Questions have been raised as to whether direct analysis cures the psychosis or merely represses it; whether the danger of producing anxiety through deep interpretation of unconscious material is as minimal as claimed; whether it is the interpretations which produce the therapeutic effect, or the personality of the psychiatrist; and whether the pa-

tient can maintain his gains. In this connection, a 10-year follow-up study of 19 of the original 37 cases treated showed that 18 had relapsed into psychotic episodes, 10 required some form of somatic therapy, and 8 continued psychotherapy. On the basis of these findings, it was concluded that direct analysis was no more effective than other standard treatments. However, in a more recent study of 14 patients treated by direct analysis, 10 were found to have made an adequate social improvement after a 5-year period. Clearly, in view of these conflicting reports, direct analysis still awaits final evaluation.

Group Psychotherapy

34.6 GROUP PSYCHOTHERAPY

ALEXANDER WOLF, M.D.

Introduction

Studies in the behavioral sciences show that we, as a society, are becoming more group-oriented in effecting individual and cultural changes. In response to this cultural process, group psychotherapy has been added to the original treatment scheme of the one-to-one, doctor-patient relationship. Although many feel that group psychotherapy further diminishes individuality in our society as well as in psychotherapy, in fact, group psychotherapy may prove to be one of the most important means of preserving the uniqueness of the individual as he struggles to adapt to complex organizational demands and yet maintain his own identity. In other words, group psychotherapy is an effective means of helping the individual to deal with the confusion, anxiety, alienation, helplessness,

and hopelessness he feels as he tries to cope with the insistent reality of increasing group pressures.

Definition. It is not easy to find a satisfactory definition of group psychotherapy. Some definitions are too broad; for example, a 1944 *War Department Technical Bulletin* states: "...any procedure which tends to improve the mental health of more than one individual, is group therapy." Others prefer a very limited definition. J. M. Cotton has written: "I would define group therapy as an attempt to reinforce and strengthen the individual's defenses against anxiety by identification with, analysis by, and support from the group." R. J. Corsini's definition lies somewhere in between the preceding two: "Group psychotherapy consists of [the] process occurring in formally organized, protected groups and calculated to attain rapid ameliorations in personality and behavior of individuals through specified and controlled reactions."

A more comprehensive definition might read as follows. Group psychotherapy is a broad designation for that form of therapy which is practiced by clinicians in groups formed for the specific purpose of helping

individuals with their psychological and emotional difficulties, the depth of such therapy depending largely on the individual technique of the therapist. According to this definition, then, social, educational, athletic, professional, and organizational groups, while they may produce positive benefits, cannot be technically classified as therapy groups.

History. Group therapy began in America as a medical experiment, rather than a psychiatric one. Between 1900 and 1906, J. H. Pratt, a Boston physician, held classes at home for tubercular patients who could not afford to be treated in a sanatorium. In these classes he gave instructions on how to keep temperature charts, on proper diet, rest, and habits of cleanliness. Pratt found that patients benefited enormously from these classes and learned to cope not only with the physical illness, but also with the emotional problems arising from the illness. Between the years 1906 and 1956, Pratt published six papers, the first titled "The Home Sanatorium Treatment for Consumptives," and the last using the term "group psychotherapy." In this period group psychotherapy evolved into an important therapeutic technique.

During the 50 years between 1906 and 1956 there was much individual experimentation with group psychotherapy techniques, much of which was never reported. However, among the significant historical dates, the following are worthy of note.

1910. J. L. Moreno began to work independently in group psychotherapy in Vienna.

1921. E. W. Lazell reported the group treatment of psychotics in institutions, using didactic lectures.

1925. Trigant Burrow introduced the term "group analysis." Burrow's studies grew out of his work with individuals and were based on his social views, plus his belief that the analyst's position in the traditional, analytic setting was too authoritarian for the mental health of either therapist or patient.

1929. Louis Wender began his work in psychoanalytically oriented groups, as opposed to educational, supportive, or inspirational groups.

1930. S. R. Slavson introduced activity group therapy, designed primarily for children between 8 and 15 years of age.

1931. L. C. Marsh reported 20 years of experience with group psychotherapy, utilizing the repressive-inspirational method and the idea of milieu therapy, which involved the entire personnel of an institution.

1934. Paul Schilder began using group psychotherapy with 50 patients at Bellevue Hospital in New York City, combining psychoanalytic and social points of view in his technique.

Historically, this was the broad setting for group psychotherapy as we know it today. The following figures demonstrate the dramatic increase in the literature published between 1906 and the present. Between 1906 and 1935, 54 publications discussed group psychotherapy. From 1936 to 1940, there were 69 publications on the subject. From 1941 to 1945, the

number jumped to 203. After 1945, the growth was spectacular. Between 1946 and 1950, 536 papers were published, and there were 879 between 1951 and 1955. Since then, publications have been still more numerous.

The cumulative impact of the depression and the tensions created by imminent war helped bring about a striking general acceptance of group psychotherapy as a treatment method. During that uncertain period, a growing number of patients who could not afford individual treatment sought treatment in group psychotherapy.

It was the Second World War, however, that gave group psychotherapy its greatest impetus. Even the United States Army encouraged the use of group psychotherapy. The following quotation is from the same *War Training Bulletin*, mentioned earlier: "The favorable response of patients to comparatively brief treatment in groups warrants widespread adoption of this method of therapy. When patients are treated promptly, a majority can be salvaged." Many individual therapists were, of course, strongly opposed to this new method of treatment. Many more, however, joined the ranks of group psychotherapists, and this number has been steadily increasing. Today, almost every psychoanalytic training school provides some instruction in group psychotherapy techniques, and many newly established schools of psychotherapy have centered their orientation around group methods.

Treatment Techniques

The techniques of group psychotherapy are almost as numerous as its practitioners. This has, unfortunately, led to some confusion. In all fairness, it must be said that any innovation calls for experimentation. Although many have tried to put various techniques of group, as well as individual, therapy to scientific test with respect to both method and cure, few can, as yet, claim scientific validation in many areas. The experiences described in the literature on group therapy are *clinical*, and will be presented as such in this section. The prevailing techniques which will be discussed here do not represent a complete survey of the multitude of individual variations now being practiced. General categories, however, are discernible and can be described. Broadly speaking, these are: (1) psychodramatic, (2) reeducational (lecture-discussion), (3) experiential-existential, (4) group dynamic, and (5) group psychoanalytic.

Psychodrama. This technique, developed by J. L. Moreno, is discussed elsewhere in this chapter (Section 34.10). Nevertheless, any survey of group therapy must at least mention it, since psychodrama is everywhere classified as a group therapy technique. Not only has it been used widely in the form originated by Moreno, it has also brought about many variations such as role-playing, which is used in group dynamics, leadership training groups, and therapy groups where imagined situations are set up and roles assigned to be

enacted by various members of the group. Some therapists use script-writing as a help in problem-solving, while others, who stress a societal orientation, employ what they call sociodrama, building their situations around such social problems as racial conflict, labor strife, gang warfare, and drug addiction, rather than around individual, emotional problems.

Reeducation (lecture-discussion). The lecture-discussion method, its definition implied in its title, is used mostly with homogeneous groups, that is, with groups made up of patients who suffer from a specific, common difficulty. Groups classified under this heading would include the following.

Patients with organic disorders. Such disorders include parkinsonism; adult cerebral palsy; and debilitating or disabling surgery, such as colostomies, removal of the larynx, and the like. Many groups comprised of patients with these problems originate in hospitals; they may continue to meet there or in doctors' offices. Although the lecture-discussion, classroom technique is most widely used, there have been reports that modified psychoanalytic approaches have been tried with success.

Patients with mental and emotional disorders. Group therapy has proved effective with institutionalized psychotic patients, the mentally retarded, patients who have received shock treatment, alcoholics, stutterers, and drug addicts. Here, too, psychoanalytic principles have been successfully introduced.

Persons with social problems. Lecture-discussion-oriented group therapy has been most successful with divorced adults (with and without children), the aged, and inmates of reform schools and prisons.

Preventive, supportive, and educational groups. Group therapy has had interesting implications for the even more widespread dissemination of mental hygiene concepts among mothers of nursery school children; mothers of children with organic, medical, and emotional disorders; parents of delinquents; expectant mothers; and certain groups of key personnel, e.g., hospital staff.

The lecture-discussion, classroom technique includes excursions into psychodrama and psychoanalytic formulations at times, but the major emphasis is on education and reeducation, and the strengthening of defenses, rather than on exploration of the personality with a view to actual character change.

These groups, unlike the heterogeneous therapeutic group, often perpetuate themselves in clubs, to assure members some kind of social life and continued mutual support. These clubs are formed not only for patients with specific symptoms, but also for superannuated neurotic or postpsychotic patients who have completed their treatment or can no longer derive any direct benefits from therapy and yet are in need of some kind of continuing care, attention, and warmth from people who understand and take an interest in them.

Experiential-existential technique. Briefly de-

scribed, experiential psychotherapy emphasizes the immediate, feeling experience of the patient, rather than his rational intellectual exploration of its meaning, history, and implications. Furthermore, the experiential therapist stipulates that the patient-therapist relationship must be a "total" one, involving the therapist to the same degree and on the same levels as the patient. In other words, in an emotional sense, the therapist becomes a patient in the group, albeit the most experienced patient and the one around whom most of the interaction is centered. He can relate to other group members or not, be therapeutic or not, as he chooses. "Only this bilateral approach," wrote Hugh Mullan in 1955, "produces sufficient anxiety to force the patient into a totally new way of responding."

According to some experientialists, conflict is an indispensable part of therapy, and one way of maintaining that conflict is for the therapist to expose his counter-transferences within the group rather than elsewhere, as more traditional schools would advocate.

In summary, the experiential technique is primarily a "here and now" technique, stressing the group as the setting for interpersonal and intrapersonal responses, with as little reference as possible to past history, experiences, or relationships. The therapist participates in the same way as the patient. Acting seems to be preferred to talking, feeling to thinking, and intuition to rationality and reason.

It is difficult to describe or differentiate the existential technique. At the outset, however, a distinction must be made between the philosophy of existentialism and the actual therapeutic technique. Many existential therapists maintain that, while their theories about humanity and its development, growth, and problems may differ from those of other schools of philosophy, their therapeutic techniques follow, or at least do not clash with, those of the schools of traditional psychotherapy to which they happen to belong. Thus, many therapists who call themselves existentialists actually practice traditional psychoanalysis in groups, with some personal variations. In contrast, others stress the methods of the experimental school, made popular by Whitaker and Malone, which focuses on group conflict and stress and which diverges at many points from more conventional forms of therapy, existential and otherwise.

The therapists who practice existential techniques also differ from most other group therapists in their emphasis on the importance of nonverbal communication. The here-and-now experience is valued above all other experience in the life of the patient. The group is considered to represent a microcosm of the outside world, where loneliness, desperation, greed, lust for power, as well as other aspects of the human condition exist. (It should be pointed out that, naturally, nonverbal communication is observed in other group therapy methods as well, but, in contrast to the existentialist approach, it is considered there to be

merely a natural part of communication, requiring neither more nor less attention than any other part.)

Group dynamics. The group dynamicists have recently gained in importance in the group psychotherapy movement. Group dynamics, fathered by Kurt Lewin, is the term originally used by its practitioners, only some of whom are psychotherapists, to describe the study of the nature of groups, the dynamics of groups, and the ways in which groups affect the individual and vice versa, in relation to problem-solving, purposes, and goals. Groups, according to the group dynamicists, have a dynamics of their own, depending on the nature, status, values, and goals of the individual members and of the leader, just as the individual's psychodynamics are shaped by his biological heritage and his historical interaction with his parents, siblings, peers, persons in authority, and, by implication, society and/or culture. Some social scientists believe that the group dynamic emphasis, when applied to education, community, and business groups, can lead to authoritarianism. Others maintain that this is an excellent method for training natural leaders and to help other members to assert themselves appropriately, i.e., to compensate for failure and to cooperate for success.

For our purposes, group dynamic therapists can be defined as those who make the group, rather than the individual, the center and focus of therapy, or, in other words, those who use techniques which focus on group themes, group relationships, group reactions, and group interactions. The writings of group therapists who have embraced group dynamics also suggest that they find techniques derived from individual psychoanalysis insufficient, and the goal of psychoanalysis (psychodynamic personality change through insight) inadequate to the group setting. Conversely, the psychoanalytically oriented group psychotherapist believes that, while group dynamics is admittedly an interesting and important subject for study by the social psychologist, it has little to offer systems of therapy for the individual. In fact, the psychoanalytically oriented therapist feels that one of the values to be gained from an understanding of group dynamics is that it alerts the therapist to certain "dangers" and thereby permits him to forestall the possible domination of the individual by the group without leaving him isolated.

Psychoanalysis in groups. The group therapy techniques described above (psychodrama, reeducation, experiential-existential techniques, and group dynamics) all borrow from established psychoanalytic techniques, in spite of their occasionally strongly expressed rejection of many of these techniques. The psychoanalytically oriented group psychotherapist finds the group setting quite different from the one-to-one setting which characterizes classical psychoanalytic treatment. However, he has not found it necessary to discard either the basic philosophy of psychoanalysis or its basic techniques. As the opportu-

nity arises, he has adapted these techniques to gain new insights which derive from a new frame of reference—the needs of the individual patient, as these emerge in response to the interaction of the group.

S. R. Slavson, an outstanding theorist and practitioner of group psychotherapy whose orientation towards the structure and function of the human psyche is based on Freud's formulations, has pointed out that treatment in a group setting "necessitated modifications as well as expansion of Freud's basic concepts," but that "these diversional necessities in no way detract or counter the profound laws formulated by Freud. It is safe to assume that were he active in the psychosocial climate of the present era and the cultural and clinical settings, and with groups, he himself would have modified his practices, though hardly his basic discoveries." Slavson then quoted a relevant statement made by Freud: "I have dug the tunnel," Freud said, "others will have to let in the light."

Relationship between group therapy and individual psychoanalytic psychotherapy. Current theories of personality have been translated into group psychotherapy, as well as individual treatment techniques. Thus, in addition to those group therapists whose techniques derive from classical psychoanalysis and neo-Freudian concepts, other more culturally oriented therapists have patterned their techniques after the theories of Horney, Adler, Harry Stack Sullivan, etc. These theoretical differences are not minimal. Nevertheless, for the most part, the techniques employed in group psychotherapy are based on the fundamental principles of psychoanalytic theory. Thus, they include exploration of the patient's personal history, to make the unconscious conscious, facilitate the expression of repressed material, and ward off tendencies to act out; the use of free association; the interpretation of dreams; and analysis of transference phenomena and resistance, with the concomitant goal of helping the patient to work through his problems so that he may achieve creative change within himself and in his relationships with others. In groups which are governed by these psychoanalytic principles, the emphasis is on the individual, and his relationships with other members of the group are studied in the light of his own neurotic history, i.e., the hostility and aggression which characterizes his object relations; his self-destructive drives; and his values, goals, and aspirations as these emerge in his interactions within the group.

Therapeutic "philosophy." This interaction, besides setting up and developing shifting relationships within the group, also elicits support for individual group members, permits catharsis, encourages reality testing, applauds insight, deplores resistance, and stimulates the courage necessary to replace old defenses with more appropriate patterns of behavior. Usually, interaction does not have to be stimulated artificially. The different and conflicting psychodynamics of the character structures in the group generally provide

sufficient provocation for such interaction. Apart from such differences, it is assumed that patients treated within the group share a consciously held common goal (therapeutic help). As their personal motivations become clearer, they are better able to evaluate the extent to which they evoke positive or negative responses from other group members, and the personality changes which are necessary if they are to achieve the specific individual goals they are striving for.

All the aspects of the patient's life are important, both within and outside the group setting, whether they refer to the past or the present; and undue emphasis on any one aspect fosters resistance. Therefore, if a patient relates only to the group or does not relate to the group at all; only to the past or not at all to the past; only to the present or not at all to the present; only to his outside life or not at all to his outside life, this is interpreted as resistance. As he becomes aware of, and is able to resolve the resistance, he will become more flexible, his capacity for change will grow, and he will then be able to meet the challenge of new choices as they open up for him.

Practical Considerations

Suitability for group therapy. Every therapist must, of necessity, differentiate between those patients who may benefit from group therapy and those who should be excluded. Slavson, for example, thinks homosexuals will not be helped in a group. Others feel that certain types of patients with character neuroses or psychopathic tendencies are best excluded. The decision is usually based either on the individual's need for personal attention, or on his potentially destructive influence on group interaction.

In general, the following formulation is useful in determining suitability for therapy. In forming heterogeneous groups, certain readily identifiable types are best excluded: serious psychopaths who may be dangerous and who always covertly disrupt the group; alcoholics who cannot control their drinking and are repeatedly intoxicated at group meetings; patients with severe mental retardation, who can frustrate the group by holding it back; severe stutterers; paranoid patients who are likely to incorporate other group members into their systematized delusions; hallucinating psychotics; and hypermanic patients. In addition, according to some authors, the group is always potentially dangerous for cardiac patients, and they should be excluded from all types of therapeutic groups. However, other therapists have included patients suffering from a variety of psychosomatic disorders in therapy groups. Moreover, patients in the other excluded categories have been found to benefit from group therapy when they are assigned to homogeneous groups, whose members suffer from the same problems. Thus, in general, patients with personality disorders, psychosomatic disturbances, psychoneuroses, and ambulatory psychotics

can be considered as eligible for some type of group therapy, as can borderline cases of any type. It may be added, in this connection, that, contrary to Slavson's findings, increasing clinical experience has shown that homosexuals respond well to therapy in heterogeneous groups.

Patient orientation. Most patients will need some kind of advance preparation before entering a therapeutic group, although on rare occasions a patient does not want or need this preparatory period. For the majority, however, individual therapy sessions should be scheduled to prepare them for this experience. The number of sessions may be limited to one or include as many as a hundred, depending on the indications. Most of these patients will have questions to ask and resistances to be explored. Some of the typical questions asked, and some answers which may be given are listed below.

Questions. (1) Will the humiliation of exposing himself to others be too much to bear? (2) Can he trust his fellow patients not to reveal his confidences to people outside the group? (3) Will he be able to share the analyst's attention? (4) And, most important of all, will he lose his individual identity by becoming "one of a crowd?"

Answers. The following reassurances usually prove sufficient to allay these anxieties. (1) The patient need never reveal anything painful or embarrassing until he is ready to do so. (2) He need never reveal his last, but only his first name. (3) He may resume individual therapy whenever he feels he needs the therapist's complete attention, unless this is a resistive maneuver. The group provides a setting in which he can be helped by others and offer his help to them in turn. He enters voluntarily and can leave voluntarily. At the same time, the group experience can help the patient to understand that his need for the therapist's exclusive attention can be traced back to experiences in early childhood, and why these should be worked through. (4) As to the preservation of the patient's "uniqueness," it can be made clear that this form of group therapy aims at the analysis of the individual in interaction with others and that recognition of the individuality of each member in relationship to himself and in communication with others is the focal point of treatment. It should also be pointed out that all therapies are directed toward the individual's self-fulfillment, maturation, and the development of responsibility, to the concomitant removal of neurotic blocks and alleviation of psychic pain. Participation in a group may help the patient to find out to what extent his "problems" are the result of his excessive need for approval and acceptance from others, or to an excessive fear of rejection; at the same time he will learn to differentiate between morbid dependence and constructive interdependence.

Size and structure of the group, and over-all organization of the treatment plan. Therapists differ on the size of the group necessary for optimal

treatment; however, it is generally agreed that a group should include between 7 and 10 patients. Most therapists also favor heterogeneous groupings (that is, men and women from different economic and social levels, and with different psychopathology).

Most groups meet once a week for 1½-hour sessions. In addition to regular meetings, some therapists include alternate sessions in their treatment plan. The therapist is not present at alternate sessions; and patients usually meet at one another's homes, rather than the therapist's office. Therapists who object to these alternate sessions maintain that patients always need the supervising authority of the therapist so that they will not act out or inflict psychic harm on each other by amateur interventions and interpretations. On the other hand, advocates of the alternate session consider it to be most valuable. They believe that its inclusion in the treatment plan helps the movement of therapy toward cure: the patient proceeds from dependence on the therapist (authority-parental figure) to dependence on his peers (the group) and then to dependence on himself, hopefully striking a rational balance between independence and a wholesome interdependence on others. If this movement can be stated as one of the goals of group psychotherapy, it can also be inferred that the patient will be able to carry over these altered perceptions of himself and others into his personal and professional life.

Combined therapy. Some therapists make combined individual and group therapy a mandatory condition of group therapy. Others feel it must be one or the other—group at the beginning, individual therapy in the middle, and group at the end. Still others see group therapy only as a terminal phase of individual therapy.

The question is really an open one, depending solely on the individual patient. Some patients are not suitable for group therapy at all; others will always need individual attention in addition to it; some will need it rarely; and some may never have to see the therapist alone during the entire course of treatment, except for the initial interview. Here again, as in other instances, generalizations should be avoided. It is even possible that there can be too much of a good thing, i.e., too much therapy.

Psychoanalytic Treatment Techniques in Groups

The literature suggests that most analysts use much the same technique in the practice of group psychotherapy as they do in individual therapy. The various divergencies in technique and in the theoretical viewpoint of the different schools of psychotherapy have been discussed briefly above. The following discussion will deal specifically with the application of psychoanalytic principles to group therapy.

Basic design. As mentioned earlier, the basis for psychoanalysis in groups is interaction. Through interaction, the psychodynamics and psychopathology of each individual can be exposed to study. To foster

this interaction, the analyst provides the setting, and in part the climate and opportunity for the expression and examination of each patient's provocative tendencies. He can help differentiate the healthy provocations, which stem from a real desire to proceed with the process of mutual discovery and interrelatedness, from those which are unhealthy and seek to exploit the group. These less healthy provocative roles are bound to appear in time. Any given group of patients will include some exhibitionists, some seducers, and some manipulators. It will include patients who cannot stand silence; compulsive organizers, who cannot tolerate formlessness or waiting; compulsive socialites, who must always keep the party going. And each of these patients will contribute to the interaction of the group. The mildly hypomanic will be stimulating, the schizoid facile with unconscious material. Even patients with psychopathic trends, who try to exploit the group in order to express their irresponsibility, defiance, and moral laxity, tend to mobilize feelings in defense. And, in their own way, even the silent members stimulate by frustration, inviting attack when they do not respond actively to invitations to participate.

While group members interact, the analyst pursues the emergence of unconscious material until each patient begins to relate his interactive thoughts, feelings, and behavior inside and outside the group to an *unconscious dynamic structure* which has a history and which is capable of being changed.

Analysis of the transference. This design of psychoanalysis in groups is based on a belief that the analysis of the bilateral transference constitutes the group's most important work. In the group setting, the patient recognizes in time that his transference represents a projection, rather than objective reality; and he gradually begins to see that his acute feelings of anxiety, irritability, depression, fear, or helplessness are inappropriate to the present moment and stem from his early relationships with crucial figures in his environment.

The concept of transference is easier to state than to grasp and work through. The analyst knows that the pursuit of transference will have to be repeated over and over again until the patient can learn to spot, chart, control, and, hopefully, work through his transference patterns.

In this, the patient is helped immeasurably by the group, as different members bring into awareness shadowy transferences (to siblings, aunts, uncles, teachers, etc.) which are peripheral to the central transferences (father, mother). It is the emergence and analysis of these multiple unconscious misperceptions, central and peripheral, that give depth and breadth to the classical theory of transference and make psychoanalysis in groups such an intensive and dramatic process.

Group process. Unfortunately, to date, the group therapeutic process has defied attempts at accurate

second hand description. Verbatim transcripts, sessions recorded on sound or video tapes, novels, and radio and television reproductions—all of these have failed to communicate the actual experience. Only training and clinical experience can convey the essence of the group process. For one thing, a "typical group session" does not exist. All sessions are atypical, except for the fact that patients compulsively repeat their psychopathology. And, in fact, one of the values of group psychotherapy is that the patient's defenses and resistances are demonstrated over and over again in different situations and with different people. Nevertheless, some broad generalizations can be attempted.

1. Each therapist will, in some measure, set the tone or climate of the group, according to his own training and personality, his resources and limitations. If he tends toward rigidity, he will establish many formal rules to govern specific aspects of the patient's conduct inside and outside the group. Another therapist, whose attitude is *laissez-faire*, will lead a group in which almost anything goes. Some will make the group itself or group dynamics the focal point of attention; others will stress the expression of irrational feelings; and still others will keep working to elucidate the psychodynamics and psychopathology of the individual patient, using the traditional tools of psychoanalysis to analyze transference, resistance, the latent content of dreams, and free associations.

2. The only session one might call "typical" is the first meeting of the group, when most patients (including the therapist) usually feel anxious. Here a standard opening question might be: "How are you feeling at this moment?" or "Did anyone feel anxious about coming here today?" This will usually bring a response, momentum will build up, and experience has shown that this momentum will usually carry over to the next session unless the therapist has set a climate which is too rigid. Indeed, it is the therapist's job to let momentum build up, so that material is released, particularly associations which are usually repressed. From that point on, he uses whatever interaction is going on to point out resistances and transferences and to open doors to alternative, healthier ways of thinking, feeling, and reacting.

3. The therapist does not "direct" the group, nor does he interrupt with premature interpretations. Generally speaking, he intervenes when verbal acting out has continued too long, when a patient is blocked or has reached a plateau, when aggressive or sexual acting out or some form of self-destruction seems imminent. General recommendations about the type of intervention most appropriate in such cases cannot be made. Each situation must be handled according to the therapist's evaluation of the individuals involved, and each situation represents a test of the therapist's training, experience, and judgment. Although it is difficult to chart a typical session, it is possible to give one example which includes verbal acting out; the building of momentum and group interaction; the in-

tervention of the therapist, and his pursuit of analytic material with analytic tools, leading to insight and some working through.

Patient *A*, a bright, accomplished woman, told patient *B*, a relatively mature, sophisticated man, that she was sorry she had missed the alternate session at his home. Patient *B*, infuriated, accused her of insincerity: since she had just entered the group, she could not possibly have a real interest in him. The therapist did *not* intervene at this point to suggest the possibly healthy (reality-bound) motives behind *A*'s remark (curiosity, a desire to be accepted by the group, etc.). Instead he let the interaction continue. *A* kept protesting her sincerity; *B* continued to lash out at her, his fury mounting, until *A*'s frustration finally reduced her to helpless tears. Some members of the group defended *A* and expressed their anger at *B*. Some sided with *B* and heaped scorn on *A*. Some berated the therapist for not taking sides, and some were bored with the whole business.

Finally, one patient asked a key question: "Suppose *A* were in fact being superficially polite? What was so terrible about that?" *B* began, through free association, to relate the situation to other instances in his life when he felt he had been duped. On the other hand, *A* was asked why *B*'s angry suspicions could reduce her to tears, and she, in turn, used free association to connect the reaction with similar experiences in her past. By this time, the therapist was also taking part, as earlier dreams were recalled and fantasies added. Finally, *A* realized that, when she was in a tight spot (with her mother) she usually used tears to escape her mother's anger. And *B* admitted, in turn, that he could forgive and forget only when he had beaten his opponent (a brother figure) to his knees. The therapist suggested that transference had played an important role in governing the responses not only of *A* and *B*, but also of other members of the group, whether or not they had actively participated, and free association continued on this level.

This is only one of many instances which could be cited where a seemingly innocent remark set off a chain reaction that was valuable for the entire group. However, it was valuable because the therapist knew when not to intervene and when intervention was appropriate. This judgment is not so difficult as it may seem, if the therapist will remember that time must be allowed for the interaction to develop and that the goal for the patient is "working through" (the discovery of healthier, more reality-bound alternatives to self- and other-defeating patterns of behavior). Because of the support she received from group members, *A*'s ego strength increased to the point where she no longer felt she had to ingratiate herself with *B* or any other members of the group, including the therapist. The reality of peerage in the group diluted her misperception of copatients as mother substitutes, so that she was no longer so threatened by them and could be more appropriately assertive. It turned out that *B* had repeatedly rejected *A* as an interloping younger sibling; moreover, as *B* saw it, *A* was favored by the therapist (whom he perceived as a brother figure). Gradually, with the help of the group members, he became conscious of this subjective distortion in successive encounters. This awareness enabled him, though not without a struggle, to view the therapist objectively and to share him with his copatients. Outside the group, *A* and *B* were similarly able to overcome these transference problems.

Working through. The working through process begins almost as soon as the patient begins to understand his psychodynamics and psychopathology and becomes aware that choices are open to him other than those created by his history and dictated by his repetition compulsion. Termination of therapy is signalled by a decreasing tendency to make self- and other-destructive transference involvements and by an increased desire to establish realistic communication under circumstances in which formerly the patient might have reacted with indifference, withdrawal, rivalry, hostility, depression, defiance, despair, submission, or collapse. The recovering patient shows growing signs of developing his own independence and authority when he welcomes responsible interdependence and when he is able to maintain his own rational opinions while accepting the views of others. In termination, as in treatment, the group provides a good setting for concrete and objective observation of the patient's progress from three points of view: the patient himself, his fellow group members, and the analyst.

Profile of the Group Therapist

The competent group therapist should be thoroughly trained. He should have a capacity for empathy and the ability to recognize and resolve his own counter-transference problems so that he can cope with his patients' neurotic responses, accept the projection on himself of a variety of transferences, and avoid, whenever possible, counter-transference misuse of the patient. The therapist should be able to admit his mistakes and avoid compulsive leadership, yet accept the responsibility of his vertical, hierarchical position in the group. Although he pursues analytic techniques, he should avoid technical terms and dogmatic, authoritarian attitudes. When patients falter, he should remain optimistic, but yet realistic; and he should react to group members with thoughtfulness, simplicity, and honesty. He should be alert to, and, whenever possible, analyze resistance, transference, and neurotic alliances within the group, without disrupting the free movement and interaction of its members.

Finally, he should be skilled in handling individual crises which call for astute resolution, such as imminent sexual or aggressive acting out between members; in coping with a patient's immediate investment of copatients with frightening, catastrophic transferences; in anticipating suicidal attempts; and in dealing with scapegoating. Efforts should be made to deal with these situations within the group setting. However, the analyst should be ready, when his judgment prompts him to do so, to transfer the patient from one group to another, or into individual or combined therapy.

34.7 COMBINED INDIVIDUAL AND GROUP PSYCHOTHERAPY

CLIFFORD J. SAGER, M.D.

Introduction

Combining individual and group psychotherapy for the same patient has become increasingly favored as the treatment of choice for many types of patients. Treatment consisting of various combinations

of individual and group therapy is applicable, in most instances, regardless of the particular theoretical bias of the therapist or analyst. Combined therapy cuts across theoretical lines and is espoused by representatives of most schools of psychoanalytic and psychological theory. The combination of intrapsychic and group process modalities utilizes two potent therapeutic forces which can deeply affect the patient's psychological status.

History. This combined method of psychotherapy is relatively new. In 1950, Klapman commented on the "shuttle" process in individual and group therapy. Fried and Papanek were among the first to utilize and describe combined individual and group therapy, and Sager elaborated extensively on the treatment technique and underlying theory. Demarest and Teicher advocated the use of a different therapist for each modality. Cappon described a method whereby individual therapy of moderate duration is followed by a terminating period of group therapy. Other authors (Hulse, Greenbaum, Bieber, and Jackson and Grotjohn) have advocated varying emphasis on special applications of either the group or individual therapy aspect of the treatment procedure. In this context, one form of therapy (usually individual), is considered to be the major tool of treatment while the other (e.g., group therapy) represents the ancillary method. Berger and Stein have elaborated on the particulars of transference phenomena in combined treatment. Finally, Redl has pointed out that an individual approach to dynamics and therapeutics is not sufficient in itself.

Rationale. Both individual and group psychotherapy contribute to the therapist's understanding and ability to help a patient. Individual psychotherapy does this largely through intensive exploration of the one-to-one (dyadic) relationship, by means of introspection and self-search and an experience with a "good" parent, the therapist. Group therapy is effective, in turn, because it provides opportunities for study of the patient's multiple transferences, identifications, and intragroup concepts and actions and because it provides an experiential framework for such change. Thus, both are potent therapeutic instruments for the clarification of those basic misconceptions of self and world which are the psychological source of much aberrant behavior.

Since a complete account of the many varieties of combined individual and group therapy practiced by psychotherapists is beyond the scope of this section, only concurrent therapy—that is, simultaneous individual and group treatment, usually with the same therapist—will be described in some detail. However, the techniques, theory, assets, and potential disadvantages of this specific form of combined therapy can be extrapolated to other types of combined treatment situations. Similarly, this form of combined therapy in particular and combined ther-

apies in general are readily adaptable to hospital, clinic, and private practice.

The Concurrent Treatment Technique

Basic formulations. Patients who have been in individual treatment for varying periods of time may have group therapy added to their therapeutic regimen. Groups usually include from 6 to 10 patients, who meet with the therapist once a week for a 1½-hour group session (some groups meet for an additional weekly "alternate" session, without the therapist).

In individual sessions with the patient, the therapist should avoid any expression of his opinion of the dynamics, symptoms, or actions of other group members, lest the patient assume that he is discussed with others in a similar fashion. If, on the other hand, such confidences lead the patient to feel that he and the therapist are cohorts, and that this makes him "superior" to the rest of the group, the effect on his therapeutic progress may be equally detrimental.

The group experience and the productions it stimulates should be treated in individual sessions in much the same way the therapist would treat other material from the patient's current life. A certain separation—and yet an obvious relatedness—between the two forms of treatment exists and has certain advantages. The kind of material to be brought to one type of session from the other depends on the therapist's sensitivity in assessing the patient's readiness to deal with anxiety-producing material. Obviously, unless his action is based on sound therapeutic considerations, reference by the therapist in group session to the "secrets" a patient has revealed in individual treatment would, at the least, close off the patient's communications. Concomitantly, if the patient feels that every time he says something meaningful in the group, the therapist will press him to elaborate on the matter in the following individual session, he will soon become a nonproductive group member. Yet, there is much material that can, and should, be exchanged between the two sessions.

Role of the therapist. The therapist's position as group leader is based on the assumption that he is not a patient. After the first few sessions, his professional training and title are not sufficient to enable him to maintain his position as leader. Rather, his continued leadership will depend on his skill and objectivity in distinguishing his role from that of the patient. In the group, the therapist's true reactions and values will, inevitably, become more apparent to his patients than would be the case in individual psychotherapy. Obviously, it is often necessary to be spontaneous; however, the analyst should screen his remarks and reactions on the basis of their therapeutic usefulness.

No guidelines can be set down as to how to conduct combined therapy. Group and individual sessions are

best conducted in the therapist's characteristic style, based on the theoretical system he has adopted. However, flexibility in technique and theory is important if the therapist is to deal effectively with the wide range of problems which will arise and which he might not normally encounter in clinical practice.

Preparing the patient for the group. Most patients readily accept the idea of entering a group, owing in part to positive transference, i.e., their "faith" in the therapist and his recommendations. And, of course, most have heard about group therapy or analysis. Patients who ultimately accept the therapist's recommendation of group therapy frequently show good insight into their problems during these preliminary discussions. Those who respond negatively to this suggestion often do so because they resent an intrusion into the uniqueness of their relationship with the therapist. Paranoid patients who have irrational fears regarding the group which have become incorporated into their system of delusions will also resist any attempt on the part of the therapist to induce them to enter group therapy.

The patient's reaction to the therapist's recommendation of group therapy may not be immediately evident. However, in the meeting which follows the session in which the subject is first broached, typically, the patient will produce one, or several, of the following reactions. (1) What appears to be a rational acceptance of the idea—and, concurrently, a lack of productivity during the treatment session. If this "blocking" is atypical, it is, of course, significant. (2) Overt anxiety. (3) Expressed feelings of rejection and/or anxiety, based on some variation of the feeling that the patient is being excluded from a unique relationship with the therapist. (4) Curiosity about the group experience and an eagerness to begin group psychotherapy, which may represent a mature reaction or a neurotic one. (5) The patient may declare his firm refusal or reluctance to join the group (which was not expressed previously). In short, the suggestion of group therapy may have stirred up latent anxieties or resistances and mobilized defenses.

For the most part, however, resistance in individual sessions which is due specifically to assigning the patient to a group is usually overcome within a few weeks. In fact, the majority of patients report a feeling of relief after their first group session. It was different from what they had expected, and not as frightening; or they actually enjoyed the experience. Many have also expressed these feelings in the group and, possibly, ventilated their initial anxieties there as well.

Nor does the introduction of group sessions to a patient in individual therapy appear to lessen the intensity of his transference reactions. As is true of other intense relationships in his life, the patient is

able to react to the therapist differently in different situations.

Indications and contraindications for combined treatment. Instead of selecting patients for combined therapy because they have done poorly or reached a "stalemate" in individual treatment, many mental health workers now regard combined therapy as the preferred form of treatment for a great variety of patients.

Almost any type of patient who is suitable for individual or group psychotherapy may profit from combined treatment. As pointed out above, the crucial point is not so much *who* as *when*, in terms of the stage the patient has reached in individual treatment. Thus, no patient should be induced to join a group at a point in treatment when he will experience this as a serious rejection and a loss of the therapist's favor. This is true, in particular, for suicidal patients. (At the same time, however, if they become suicidal subsequently, the group can often be most helpful to them.) This form of treatment may also be contraindicated for certain patients with marked hostility who act out much of their anxiety. Such patients often find the group experience very frustrating and may make life extremely unpleasant (and nontherapeutic) for the other group members. Fortunately for their copatients, if not for themselves, they do not tend to remain in combined treatment for long.

Therapeutic Process

At first, recordings of the same patient in both individual and group situations may well sound like two different patients, working with separate therapists. Only after careful attention to the latent content of the material can one see the connections between one form of therapy and the other, and how these reflect different aspects of the same individual. As therapy progresses, the relationship between the material covered in each setting emerges even more clearly: although frequently they do not appear to be related on a conscious level, the unconscious parallel lines of therapy begin to converge. As therapy proceeds, these lines approach each other more and more closely, until the patient arrives at an actual insight and undergoes a major change in conceptualization and behavior, or until his altered underlying concepts effect spontaneous changes in his behavior without the formal verbalization of an insight.

One of the most fascinating aspects of combined group and individual therapy lies in the fact that it enables the interrelationship of insight and interaction to facilitate change in the patient. Insight is generally considered to be the major means of producing beneficial behavioral changes in patients in analytic types of individual treatment; interaction is believed by many to be the major instrument of group therapy. Yet both insight and interaction are

continuously operative in both forms of treatment, even though the therapist may emphasize one rather than the other.

Expressed differently, much of human behavior involves the individual's adaptation and reaction to others. Significant interactional experiences may or may not have been formulated into concepts. When concepts have been formulated, these must be retained on a conscious or unconscious level. In these cases, individual psychoanalytic therapy can be very useful. When significant experiences have not been conceptualized, the experiential aspects of group therapy often lead to more constructive results. When they are used in combination, the value of each treatment modality may be enhanced.

34.8 FAMILY THERAPY

NATHAN W. ACKERMAN, M.D.

STEPHEN W. KEMPSTER, M.D.

Introduction

Definition. Family therapy derives from two fundamental propositions. First, the family is conceptualized as a behavior system with unique properties, rather than the sum of the characteristics of its individual members. Second, it is postulated that a close interrelationship exists between the psychosocial functioning of the family as a group, on the one hand, and the emotional adaptation of its separate members, on the other. Family therapy has evolved from these propositions as an approach to the link between disorders of family living and the disorders of individual members of a family by means of dynamically oriented interviews of the entire family population. This is based on the assumption that these individual emotional difficulties stem from disturbances in the over-all interaction of the family. More specifically, then, treatment focuses on the family as a natural biosocial unit and encompasses all the persons within that unit (including grandparents; extended kin; and others who are not consanguineous, but who, nevertheless, play a significant role in family life—as well as the "crucial" figures in the family organization).

Goals of treatment. Broadly conceptualized, family therapy reflects this theoretical orientation in that the family therapist seeks to relieve emotional distress and promote mental health in the family as a group, as well as in its individual members. Accordingly, the goals of treatment may be delineated as follows: (1) to resolve or reduce pathogenic conflict and anxiety within the matrix of interpersonal relationships; (2) to enhance the perception and fulfillment by family members of one another's emotional needs; (3) to strengthen the immunity of the family against external and internal crises; (4) to promote more appropriate role relations between the sexes and between the generations; (5) to strengthen the capacity of individual members and the family as a whole to cope with destructive forces from within, and from the surrounding environment; and (6) to influence family identity and values so that they are oriented toward health and growth.

History of Family Therapy

When psychotherapy is viewed in historical perspective, one can detect a progressive change in orientation. Thus, the emphasis on individual symptoms and conflicts has shifted to the evaluation of total personality functioning, to the relationship between

personality development and role, and, finally, to the significance of patterns of family and community organization as factors in the pathogenesis of mental illness. The development of family therapy as a treatment method (and its subsequent contribution to community mental health programs) was a logical consequence of these progressive changes in orientation. At the same time, if the widespread implications of these therapeutic innovations and the factors which propelled them into being are taken into consideration, the evolution of family therapy can be attributed to a number of confluent forces. These include (1) revolutionary transformations in traditional family patterns, induced by social change and accompanied by increasing signs of disordered human relationships both within and outside the family; (2) recognition of the validity of the principle of contagion of emotional disturbance and, concomitantly, of the direct relationship between social and emotional disorder; (3) greater awareness of the limitations of conventional methods of diagnosis and treatment as they relate to the individual patient; (4) new developments in the behavioral sciences, specifically in ego psychology, small group dynamics, social psychology, anthropology, and communication; and (5) the changing role of the psychotherapist in the community.

Treatment Method

At present, family therapy is still in an experimental stage. Consequently, its principles are being applied in diverse ways to a wide range of family problems by therapists who frequently differ in basic orientation. Nevertheless, some universal principles can be formulated.

The presenting problem. An evaluation of family interaction and of the behavior of its individual members will frequently disclose evidence of long standing pathology. Nevertheless, as long as the emotional functioning of the family retains some semblance of balance, there is no urgent need for psychiatric referral. The timing of the demand for professional help coincides with the immediate, dramatic impact of a decompensation of the previous state of balance, which, in turn, results in a distressing family conflict. Critical upset of the emotional equilibrium of the family as a group is often a significant indication of the psychiatric illness of one, or several, of its members.

The family members feel that something is deeply wrong, but they do not know what, or why; nor do they know how to rectify the situation. Customarily, one of the members is pushed forward as the sick, disabled one. However, in actuality often several and sometimes all of the members of the unit are disturbed albeit in different ways and to different degrees. What the psychiatrist faces then, is a cluster of psychiatric illnesses which involve interrelated and interlocking processes.

Whatever the presenting complaint, and regardless of which member is labeled "the sick one," the entire family is invited to come in and "talk it over." Subsequent therapeutic interviews may be conducted either in the therapist's office or in the patients' home. Traditionally, families are seen once or twice a week for about an hour.

Intake and diagnosis. For obvious reasons, the more traditional intake and diagnostic procedures may be unsuitable. It is preferable, instead, to initiate contact with the whole family in a fresh, unprejudiced way, without having obtained historical data beforehand from its individual members. As the group wrestles with its immediate distress, a kind of living history emerges which is apt to be more relevant and meaningful than the data elicited through traditional history-taking procedures.

In the course of the "therapeutic struggle," and particularly during induction, when anxiety may be at a high level and defenses relatively ineffective, selected historical fragments are volunteered by individual members of the family and consensually validated or invalidated by the group. The evaluation of these spontaneous historical disclosures constitutes a meaningful experience for the therapist. Factors of pathogenic significance which derive from the past can be identified in the contemporary emotional crisis of the family, although they may now be organized and expressed in a different way. In fact, the importance and relevance of this historical information hinges on the ability of the therapist to place it in proper perspective as an active part of the present. This is not the "dead past"; rather, it is the "live past" of the family, which poignantly illustrates the interrelationship of family dynamics and individual psychiatric disorder.

It follows, then, that family diagnosis and therapy are interwoven, parallel activities. The heightened intimacy which characterizes the family treatment interview enhances the therapist's insight into the pathogenesis and varied symptomatology of emotional disorder, just as it increases his understanding of the dynamics of behavior.

Initial interview. Diagnosis and therapy begin with the therapist's first face-to-face contact with the family. At the outset, families present themselves in extraordinarily diverse ways. Some hide behind a facade or are self-protecting and withholding. Others seem tense and troubled or are frantic and panicky; still others act as though they may "explode" at any moment. The therapist formulates his initial observations of the personalities of the various family members, their way of interacting, their adaptation to family roles. How do they enter the treatment room? Who sits next to whom; who looks toward whom; who looks away from whom? Who speaks; who listens? Who smiles; who frowns? Typically, the family arrives at the initial therapeutic sessions in a

state of tension, apprehension, and frustration. The therapist quickly senses the emotional climate, and the quality and intensity of the appeal the members of the family extend to one another, and to him. Who wants what, from whom? Do they deny and disguise their needs or express them in an urgent, coercive way? Have they simply given up and, in a mood of resigned apathy, ceased to ask for or expect anything from anyone? Above all, the therapist notes the existing confusion, distrust, and fragmentation of family relationships.

During this initial phase of therapy, what one parent conceals, the other may reveal. What both parents conspire (consciously or unconsciously) to hide, the child may blurt out. When one member describes his experiences or reactions in a distorted manner, these distortions are often corrected by another. When certain anxiety-filled material is touched upon, the family may engage in a silent pact to avoid these areas. Sooner or later, however, such denials are broken through. Family life, by its very nature, is inimical to the guarding of personal secrets. It is the clinician's responsibility to distinguish appropriate efforts to maintain privacy from pathogenic secretiveness, and to respect the former while he supports the family's attempts to pierce the latter.

Role of the therapist. The function of the therapist is multiple and complex and calls for a flexible use of self; for the family, through all its parts, selectively interacts with, absorbs, and uses his influence in a variety of ways. Depending on the changing patterns of conflict and anxiety, one or another member identifies with, or withdraws from, the therapist. These partial joinings and separations reflect elements of transference, fantasy and reality. The therapist, in turn, must shift his influence from one member of the family to another, following the path of the core of the most destructive conflict. In this way, he is able to stimulate increased awareness of the true nature of the emotional and social disturbances which confront the family unit and, concomitantly, to stimulate the unit to engage in the progressive process of resolving related conflicts.

The family unit possesses a "body," "mind," and "spirit." It has both depth and surface expression, an inner face and an outer face. Initially, its members wear a mask, but when the mask is removed, one can glimpse the inner structure and conflict experience of the family. To do so, however, the therapist must be alert to his own emotional idiosyncracies. Only if he has achieved such self-awareness will he be able to distinguish clearly between his own private reactions to the family and his objective evaluation of their behavior. Obviously, the therapist's image of the family, as opposed to the family's image of itself, is of crucial diagnostic importance; the objective validity of that image will depend on his ability to interpret the accuracy and appropriateness of the emotional

reactions the family evokes in him within the treatment setting.

Course of therapy. Briefly stated, family therapy emphasizes the principle of emotional contagion in family process and the constrictive consequences of fear, guilt, and hostility. The therapist's efforts are guided by his awareness of the pathogenic conflict and means of coping with each other, as well as the transmission of love and positive strengths.

On the basis of these principles of transmission, family therapy clarifies the significance of multiple interactional disturbances among the members of the family group. In addition, family therapeutic techniques permit evaluation of individual adaptation as well as over-all family development. Delineation of the distortions of interactional patterns permits assessment of the relationship between the emotional functioning of the family group and the potential emotional growth of its individual members.

Of necessity, family therapy usually begins with superficial interpretations and intervention, but it can attain greater depth. In fact, the competent therapist can achieve access to any level of psychological functioning he feels must be investigated to resolve the problems of a particular family. The success with which he elicits data and explores components of the experience of the family group in depth will depend, ultimately, on the efficacy of his therapeutic techniques and the appropriateness of his therapeutic goals.

Above all, the therapist seeks to transpose intrapersonal conflict and anxiety to the level of active interpersonal exchange. To this end, it is his responsibility to stimulate interaction among the family and to effect meaningful emotional interchange. As individual members of the family begin to feel closer to the therapist, they tend to establish closer relationships with one another. In the course of his efforts, the clinician integrates and applies his knowledge of the psychodynamics of human behavior, of his therapeutic function, and, finally, of his self-awareness, in special ways. He is a participant in the family interaction, as well as an observer. His role is a dynamic one; thus, he moves directly into family conflict to engage in and influence interactional processes, withdraws to objectify his experience, and then moves in again. Weighing and balancing the healthy and sick forces, he supports relatedness and health while counteracting alienation and sickness.

Frequently, in the early phase of therapy, the family engages in a vicious cycle of attack, defense, and counterattack; some members consistently hurl accusations and blame others for their "plight"; the "martyrs" in the group express their righteous indignation. Or, conversely, there may be a shared apathy and depression. The therapist evokes increasingly candid disclosure of the currents of conflict and, concurrently, attempts to temper its destructive fea-

tures: sniping and bullying, evasions, denials, and diversionary tactics are firmly challenged. The tendency to bicker over trivial, irrelevant external issues as a form of resistance is counteracted. The therapist tries to foster empathy among family members; he invites them to make an honest effort to understand one another's needs. Step by step, as the therapist exposes and challenges denials, displacements, and rationalizations, the essential conflicts emerge in clearer perspective. And, as this occurs, the therapist elicits greater cooperation from family members in the shared search for solutions, or more appropriate compromises, to these conflicts.

Concomitantly, the therapist seeks to neutralize prejudicial assault and scapegoating. One part of the family is mobilized to attack and sacrifice another part. If he is able to expose and counteract this special defense against anxiety, the therapist can interpret the underlying conflict in terms of its place of origin in the family group; that is, the conflict can be traced back to its primary source. During this phase of therapy, one member assumes the role of punisher; another that of victim and scapegoat; a third emerges as the "healer" and peacemaker in the family war. The therapist joins forces with those family members who represent the "healing" trends. As both the family and therapist begin to distinguish between areas and forces of conflict and coping, it becomes necessary to explore in greater depth the interplay between group defenses and individual defenses against anxiety.

To this end, the therapist uses confrontation as a therapeutic tool in a variety of ways. He penetrates and undermines pathogenic defense mechanisms. He exposes certain defenses as ineffective, inappropriate, and harmful and thereby fosters the substitution of healthier means of coping with anxiety. He encourages more meaningful communication among family members by interpreting the nonverbal aspects of communication, as reflected in gesture, mood, and expression. This procedure serves to counteract the tendency to use words to conceal rather than to reveal, to substitute empty verbal expressions for genuine emotional interchange. In brief, the family is confronted with the conspicuous inconsistencies and contradictions between verbal utterance and physical expression which characterize their relationships.

The informal atmosphere of the treatment setting and the therapist's periodic attempts to inject some humor into the situation are effective means of piercing pathogenic defenses, for these factors ease tension, increase participation, and reduce resistance. On another level, however, the therapist protects the family against interpersonal danger. Through his very presence, he offers the necessary reassurance against the threat of explosions of anger, loss of control, panic, and disorganization. When it is needed, he offers acceptance, understanding, affirmation of

worth, and direct satisfaction of valid emotional needs, first to one member, then to another. As a general rule, weaker members are supported against attack from stronger members.

At still another level, the therapist provides the family with elements of emotional imagery of themselves and of others, which had been absent previously. Moreover, he continually provides family members with new opportunities to test and retest their perception of one another and of the family as a whole.

Finally, family therapy is an educational process, and the therapist serves as a personal symbol of family health. Accordingly, he attempts to shift the focus of discussion from disagreements about who is right and who is wrong, who is sick and who is well, to broader issues. Who is receptive to others; who tries to advance the further growth of both the family and its individual members? Step by step, barriers of isolation, aggression, and guilt are penetrated. The therapist encourages mutual concern among family members and is alert to expressions of affection and the desire for true closeness. When preexisting alignments have been disrupted, and "splits" repaired, the way is opened for new designs for family living which offer mutual satisfaction and a greater potential for the future growth of the family as a whole. The family members discover a new sense of loyalty which enables them to identify with and support one another's development.

Indications and Contraindications

Family therapy can be applied as the sole method of treatment, or in conjunction with other techniques, to a wide range of behavior disorders. Thus, it has proved effective in the treatment of psychosis, neurosis, and character disorders, especially the acting out type. This type of therapy fosters the understanding and resolution of emotional illness which provides secondary gains. And, as might be expected, it is uniquely effective in disorders involving marital conflict or conflict between children and parents. On still another level, it can be a useful technique for involving a disturbed and resistant family member in a therapeutic experience. In addition, it can be of value at various stages in the individual psychotherapy of a specific member of the family, in that it may help to decrease the resistance which has hampered his therapeutic progress. Finally, in this connection, family therapy may facilitate the reintegration of a patient within his family group in the final phase of his personal therapy, or following (or during) hospitalization for psychiatric illness.

Contraindications to family therapy are few, and these are relative rather than absolute. One such contraindication is evidence of an irreversible trend toward the breakup of the family. Viewed realistically, for some families, it may be too late to re-

verse the process of fragmentation. Another contraindication is the dominance within the group of an unyielding destructive motivation. If, for example, one parent is afflicted with an organized, progressive paranoid condition, is an intractable psychopath, or a confirmed criminal, family therapy may be contraindicated. It is also contraindicated if either or both parents are unable to attain a sufficient level of honesty, and if their lying and deceitfulness are deeply rooted and irreversible. Another possible contraindication is the existence of an unyielding cultural or religious prejudice against this form of treatment. Finally, organic disease or other serious disability of a progressive nature, which precludes the effective participation of one or more members, may be a contraindication to family therapy.

Suggested Cross References

For a discussion of the relationship between family factors and behavior see Section 4.3 by Fleck on the role of the family in psychiatry, in Chapter 4 on basic sociocultural sciences (Area B). The role of family factors in the etiology of psychosis (specifically, schizophrenia) is explored at length by Weiner in Section 15.3 in Chapter 15 on the functional psychosis (in Area F, on the nosology of psychiatric clinical syndromes).

34.9 MULTIPLE THERAPISTS

JACK L. RUBINS, M.D.

Introduction

In the therapeutic situation described herein more than one individual assumes a structured, therapeutic role toward one or a group of patients.

Treatment techniques. A variety of techniques has been used. In addition to the therapist, there may be a silent observer who plays a definable, dynamic role in relation to the treatment situation but who, in fact, has no further responsibility than to take notes and report to the therapist. There may be two therapists (dual therapy), i.e., a psychiatrist and a psychologist (or social worker, nurse, or student), of either the same or opposite sex. Both therapists may be present at the same treatment sessions, or they may alternate. They may be assigned the same degree of responsibility, activity, and role, or they may assume different roles and functions. There may be three therapists (triple therapy), each with a different function. For example, one may be more active than the others; one may handle intragroup situations while the others focus on environmental problems; and one may handle material elicited in the dynamic treatment situation while the others deal with material relating to the patients' extratherapeutic existence. Finally, several psychiatrists may treat one, or several, patients, in a variation of the therapeutic team approach, each being free to function in his own way.

Just as the number of patients being treated simultaneously by several therapists may range from a single patient, to a small group, to a large group, the form and structure of the group may also vary: all the members may be the same sex, or they may be of different sexes; they may all be about the same age, or their ages may vary; they may represent similar and/or widely diverse clinical entities; the patients in the group may be related, i.e., by marriage or as members of the same family, or they may have been strangers previously.

On the other hand, the criteria used in the selection of patients for treatment by multiple therapists may apply to the type of patient or problems. Such groups would be restricted to children or adolescents with similar problems, such as delinquency, acting out, sexual, or school problems. Similarly, membership might be limited to geriatric patients, to schizophrenics, to patients with various other forms of psychosis, or to patients who share certain specific problems in common, e.g., extreme aggression or mutism. By the same token, psychoneurotics whose illnesses have taken the same form, e.g., obsessive-compulsive,

pulsives, may be assigned to the same group, as may those patients whose situations are analogous in other respects, e.g., lack of progress in individual therapy.

Rationale. The rationale for the use of multiple therapists and for the functions of therapist and co-therapist will vary, depending on the cotherapist's role in the treatment situations, e.g., as observer or equally active. In general, however, the use of several therapists is considered to serve the following purposes: (1) it may accelerate or enhance the effectiveness of therapy; (2) a cotherapist may facilitate the activity of the therapist by providing him with emotional support; and (3) it may serve as a training experience for a cotherapist. The observer-cotherapist, in turn, performs specific functions which are considered to implement these aims. (1) He adds an extra dimension to the observations and acumen of the therapist. (2) The cotherapist may keep records for therapeutic purposes, such as furnishing feedback to the group. (3) His efforts may foster research. (4) The cotherapist may be assigned to supervise the therapist. (5) Finally, the cotherapist(s) may be aware of elements in the behavior of the group which have escaped the therapist's attention and which can then be discussed after the group meetings.

Advantages. When the therapist and cotherapist assume equal responsibility in the treatment situation, their relationship produces changes in the dynamics of the therapeutic process. It is these changes which justify the use of this technique. Thus, from the Freudian viewpoint, the use of multiple therapists is considered to produce the following advantages. (1) With respect to the individual patient, transference feelings develop more quickly and are more accessible to observation and analysis. (2) Furthermore, transference feelings exhibit greater variation. The patient reacts to each therapist as a transference figure. In addition, he reacts to the two therapists as a couple. Finally, he may have transference feelings toward the other patients in the group as well. (3) Such feelings can be split. Thus when the therapists are of opposite sex, thereby reproducing the family constellation and evoking male- and female-associated attitudes, transference phenomena in patients with problems of sexual identity or in children whose family relationships have been inadequate may be particularly significant. On the other hand, when the cotherapists are of the same sex, or they participate in alternate sessions, they may be perceived as a good-bad emotional constellation, so that one therapist is seen as an ally and the other as an enemy. In such cases, hostility can be diffused and thereby diluted for easier management. (This is of special value with paranoid or depressed persons.) (4) Learning is facilitated, and communication enhanced. And, of particular importance for marital and family therapy, both patient and therapists

achieve a more complete and accurate understanding of the patient's personality. (5) Blocking and resistance are avoided or, at least, overcome more easily. (6) Finally, the termination of therapy is less "traumatic."

In addition to these dynamic effects, certain practical advantages are cited: for instance, this therapeutic method allows for vacations or illness of a therapist without interrupting therapy; more than one immediate source of help is available (e.g., for suicidal patients); attendance at alternate sessions represents a time saver, in terms of his professional commitments, for each therapist; the method furnishes emotional support for the therapist who is anxious about leading a group or fearful of making mistakes or of being attacked by patients; and, finally, it is claimed that this method provides "on-the-job" training, so to speak, for the cotherapist.

Limitations. Nevertheless, the use of multiple therapists has obvious limitations which must be considered. These include (1) the cost of the services of several therapists, as well as the additional time required and the administrative problems involved; (2) the danger of creating undesirable transference relationships, or of splitting the group through identification with one or the other therapist, or of one or the other therapist being drawn into a family conflict; (3) the problems arising from neurotic attitudes of each therapist toward the group or toward each other (e.g., conflict in role, leadership competition and rivalry, problems involving the prestige attached to senior as opposed to junior status); and (4) the danger that the anxieties of one therapist might undermine therapy.

In brief, it is generally agreed that the use of multiple therapists requires a high degree of competence, maturity, flexibility, emotional stability, and mutual trust on the part of the individuals involved.

Suggested Cross References

The reader may supplement his understanding of this treatment procedure by referring to the other sections on group psychotherapy in this chapter and, in particular, to Sections 34.8 and 34.10 on family therapy and psychodrama, respectively.

34.10 PSYCHODRAMA

JACK L. RUBINS, M.D.

Definition. (Psychodrama is primarily a form of group psychotherapy which involves a structured, directed, and dramatized acting out of the patient's personal and emotional problems, as well as his immediate group interaction problems, using definable techniques.) Although originally promulgated by Moreno in the specific context of his psychodramatic and sociometric theories, it has since been modified by him and by others, using different psychological (Jungian, Pavlovian, hypnotic) and psychoanalytic (Freudian) theories.

Forms of psychodrama have been used with children and adolescents; with schizophrenics; with neurotics showing motor pathology, such as stuttering or ties; with individuals who have marital and family problems; with homosexuals and similar patients, as a reconditioning-behavioral technique; and with professional actors who wish to achieve greater freedom of self-expression. In itself, however, psychodrama is not acting in the theatrical sense. The goal of psychodrama is self-realization, not the development of effective facades.

Underlying principles. Psychodrama is based upon the underlying principles that action and/or dramatic psychotherapy permits greater depth and breadth of awareness than is obtainable through verbal means. It includes such procedures as catharsis, abreaction, free association in acting, and the "encounter" between persons. Interpretations may be used but are not often needed. The major goal is not insight. Rather, psychodrama seeks to promote spontaneity, total perception of unhealthy responses (both verbal and nonverbal cognitive patterns), a more accurate perception of reality, facilitated involvement with other persons, and learning through experiencing.

The Elements of Psychodrama

The group. The group (i.e., the audience and the participants) shows a certain configuration of personalities in patterns of interrelations and behavior. This group can be described by means of a sociogram (the diagram portraying the forces of attraction, repulsion, and indifference in the group), which serves as the guide for the therapeutic process in drama. The group must be moved toward acting out through a warm-up, which may take one of three forms: (1) the cluster warm-up, in which different discussion groups merge into a single predominant one; (2) the association warm-up, where a chain of ideas leads to a final theme; and (3) the directed warm-up, in which an already familiar topic is introduced for portrayal.

The protagonist. The acting subject (the patient), who is described as the protagonist, must be motivated by some need, such as relief from anxiety or frustration in a real-life situation; desire for mastery; or the wish for self-realization. Resistances to participation may be due to private fears, social or ethnic conflicts, or symbolic problem areas, and they must be overcome by specific techniques.

The director. The director, or therapist, leads the production in accordance with clues provided by the patient, instructing all the performers as to their roles. Moreover, his own role will vary with the dramatic situation; more specifically, he must constantly change his role so that the patient's maladaptive patterns can be brought out and corrected. The relationship between the patient and therapist is described not only as transference, but also as telic; that is, the patient has a direct, primary, intuitive feeling about the immediate behavior of the therapist.

Auxiliary egos. Auxiliary egos are other persons in the group who act out the roles assigned to them by the director, in order to intensify the impact or clarify the meaning of the therapeutic situation. These persons represent the patient's perceptions of the significant people in his environment. The drama may focus on a special area of functioning such as a delusion or hallucination, a dream, a family or community situation, a symbolic role, an unconscious attitude (e.g., oedipal), or an imagined future situation.

Techniques. Finally, the fifth element of psychodrama is the use of various techniques to advance therapeutic progress, productivity, and creativity. Important among these are the soliloquy (a recital of hidden thoughts and feelings, together with overt ones), role reversal (the exchange by the patient of his role for the role of a significant other persons), the double (an auxiliary ego acts like the patient), the multiple double (several egos act as the patient did on different occasions), and the mirror technique (an ego imitates the patient and speaks for him when he cannot act for himself). Other modifying techniques include the use of hypnosis (hypnodrama), thiopental sodium (Pentothal sodium), alcohol, insulin, or pentylenetetrazol (Metrazol) to modify the acting behavior in various ways.

Chapter 35

Organic Therapies

35.1 TRANQUILIZERS IN PSYCHIATRY

HERMAN C. B. DENBER, M.D., Ph.D.

Introduction

Historical background. A paper presented by Delay, Deniker, and Harl at the centenary meeting of the Société Médico-Psychologique in Paris, on May 26, 1952, entitled, "The Therapeutic Use of a Phenothiazine with Selective Central Action (RP 4560)," began a new era in the treatment of psychiatric disorders. Although Hamon and his co-workers had used chlorpromazine previously in conjunction with barbiturates for manic excitement, their relatively mediocre results did not anticipate the potential of this series of compounds. A short time afterward, in 1954, Kline introduced rauwolfia for the treatment of psychiatric disorders. Since then, the use of pharmacological agents in psychiatry has been the subject of several national and international conferences.

The Neuroleptic Drugs

Definition. While these compounds have been collectively labeled "tranquilizers" (or "major tranquilizers"), perhaps as a result of initial observations of their effect on extremely disturbed patients, it should be borne in mind that this misnomer obscures their real activity. The term "neuroleptic" would seem to be more appropriate, based on the following criteria: (1) marked sedation, without sleep; (2) effectiveness in the most intensely agitated and excited patient; (3) progressive disappearance of symptoms in acute and chronic psychoses; (4) extrapyramidal reaction; and (5) subcortical site of action.

Action. The neuroleptic drugs not only relieve anxiety and calm the psychotic patient, but more specifically influence the acute or chronic psychotic process. These antianxiety and antipsychotic effects are not necessarily synchronous in action, although this is possible. It is equally possible to observe one without the other. Whether or not this is a transitory

or a permanent effect is not the issue. Treatment with therapeutically active doses over a period of time results in the gradual recession of various symptoms in a majority of patients.

General considerations. Pharmacotherapy in psychiatry cannot be considered in a vacuum, in the context of "one pill—one patient." Innumerable variables enter into the total field surrounding selection, prescription, administration, and psychodynamic meaning to the patient, as influenced by the family and environmental pressures. Secondary anxiety may develop in response to side effects, which, if misinterpreted, may be seen as a clinical aggravation and lead to increased dosage. This, in turn, can increase anxiety, eventuating in a panic state. The homosexual patient may view chlorpromazine as a drug that will sedate him to the point where "his defenses are down." Some will feel that the extrapyramidal reaction is equivalent to paralysis, which they imagine as being permanent, even leading to death. The nursing staff, or relatives, must be indoctrinated into the nature and reasons for chemotherapy; otherwise, in compassion for the patient's apparent "suffering," they may "forget" one dose or more, if not all of the medication. Finally, the unconscious dynamics of the treating psychiatrist become important, since he will prescribe as a function of his feelings about drugs and psychiatric treatment. If wholly psychoanalytically oriented, and forced by the pressure of circumstances to order chemotherapy, ineffective doses will be used; this will tend to prove that "drugs are not good." If the opposite orientation is true, the psychodynamics of a particular drug reaction will not be understood and appropriate treatment will also be without effect.

Drugs must be used in effective doses, based upon previous clinical investigations and personal experience. Small amounts should not be given because the psychiatrist is "afraid of side effects." It would be more advisable, perhaps, for the psychiatrist to become aware of his own feelings regarding treatment in general. The prescription of drugs for psychiatric disorders must be made by a qualified medical practitioner only and requires continuous clinical observation. This cannot be delegated to or be done on

1252 Organic Therapies

behalf of a third party. Dosage must be regulated frequently, at times on a daily basis, and toxic effects must be treated immediately in order to avoid any serious consequences.

Young and old patients must be treated differently. Children require higher than average dosage. Older patients will require lower amounts, but careful follow-up is necessary at all times with drug-treated senile patients.

Classification

Chemical structure distinguishes various groups of neuroleptics and other drugs most commonly used in practice today (Table I). Group I comprises the non-halogenated phenothiazines, and Group II the halogenated phenothiazines. Group III contains the largest number of compounds and is distinguished by a piperazine side chain. The compounds in Group IV have a side chain component on the aliphatic chain attached to the nitrogen of the phenothiazine nucleus. Group V consists of the methylpiperidine derivatives, and Group VI the thioxanthines. Group VII are the butyrophenones, which are used widely in Europe but still considered experimental in the United States. Group VIII includes the diphenyl derivatives. Finally, Group IX comprises the rauwolfia compounds.

The different drugs may be distinguished on the basis of clinical activity and side effects. While there is some evidence that particular drugs may affect specific symptoms or diagnostic entities, much work must still be done to clarify this matter.

Indications for Neuroleptic Drug Therapy

Acute schizophrenia; manic, involutional, and senile psychoses; agitated states (associated with toxic-confusional syndromes); agitated depression (particularly in the involutional states); acute alcoholic and epileptic psychoses, as well as psychoses due to mental deficiency where psychomotor disturbances are predominant; psychoses due to organic brain disorder (e.g., arteriosclerotic brain disease, chronic brain syndrome); Parkinson's disease; Huntington's chorea; the acting out phase of psychoses associated with psychopathic personality; and the chronic psychoses are major indications for neuroleptic therapy. Reserpine is particularly indicated in acute manic excitement.

These drugs are equally indicated in the borderline states—those patients with extremely weak ego strength and fragile reality adaptation, whose defenses crumble under minimal pressure, precipitating an acute psychosis. The childhood schizophrenias and adolescent character disorders with a marked emotional component represent other areas of application. The evidence is less clear for the psychoneuroses. While good results have been obtained in the severe obsessive-compulsive neuroses, chronic anxiety states, hysterias, etc., the results are less certain for the milder

states. While it has been claimed that depression represents a contraindication to the use of neuroleptics, this has not been borne out clinically. Previous and present studies indicate the contrary. However, rauwolfia should not be used, for it can aggravate preexisting depression.

Treatment may be directed to the following symptoms, regardless of diagnosis: tension, anxiety, hyperactivity, agitation, restlessness, impulsiveness, aggressiveness, assaultive and destructive behavior, and auditory or visual hallucinations. Neuroleptics are particularly effective against the paranoid and hallucinatory episodes in all psychotic behavior. Neuroleptic medication may be necessary, and should be used, in psychotic disorders which occur following surgery or are associated with myocardial failure or infarction, ulcerative colitis, and pre- or postpartum psychoses.

Treatment Procedures

The psychiatrist faced with the problem of treating an acute or chronic psychiatric patient must ask several questions.

Which drug would best fit this symptom complex? It has not been possible to predict the nature of the patient's response to a specific drug. The choice of one drug over another has been empirical and, curiously enough, some patients have been treated with a series of compounds before finally responding. Nevertheless, some general principles can be formulated:

If the patient is an acutely disturbed, hallucinating schizophrenic, then chlorpromazine, trifluorpromazine, or thioridazine would be the choice. If the patient is an apathetic, retarded, withdrawn catatonic, a piperazine phenothiazine would be indicated. A chronic psychiatric patient would require more potent drugs (that is, theoretically more potent, on a dosage basis), such as prochlorperazine, trifluoperazine, fluphenazine, or perphenazine, etc.

Mepazine, promazine, and chlorprothixene are considerably inferior in potency to the other compounds. Azacyclonal and hydroxyzine are available but are considerably less effective. The use of rauwolfia has decreased markedly since its introduction.

Of all the neuroleptic drugs, chlorpromazine is easily the most widely used; it has a good safety margin, and is applicable in both acute and chronic psychoses. In fact, however, the National Institute of Mental Health-Psychopharmacology Service Center Collaborative Study in 1964 showed that there were no significant differences among chlorpromazine, thioridazine, and fluphenazine, on any of their "25 measures of clinical activity." The results seemed to support the hypothesis that the other two drugs were "generally as effective clinically as chlorpromazine." A comparative study by Lasky et al. of chlorpromazine, chlorprothixene, fluphenazine, reserpine, thioridazine, and trifluorpromazine showed that none of the

TABLE II
Neuroleptic Drugs in Current Psychiatric Use
in the United States

Generic Name	Trade Name	Dosage Range (mg./day)
Acetophenazine.....	Tindal	40-80
Carphenazine.....	Proketazone	25-400
Chlorpromazine.....	Thorazine	75-1,000
Chlorprothixene.....	Taractan	30-600
Fluphenazine.....	Permitil, Prolixin	5-30
Mepazine.....	Pacatal	75-600
Perphenazine.....	Trilafon	16-64
Prochlorperazine.....	Compazine	30-150
Promazine.....	Sparine	150-800
Thiopropazate.....	Dartal	10-100
Thioridazine.....	Mellaril	300-800
Trifluoperazine.....	Stelazine	15-40
Triflupromazine.....	Vesprin	30-150
Rauwolfia compounds		
Deserpidine.....	Harmonyl	0.1-5
Rauwolfia serpentina.....	Raudixin	50-300
Reserpine.....	Serpasil	0.5-20

differences among the six drugs were significant. Reserpine, if anything, was the least effective.

Although these drugs all seemed to be equipotent, many patients in clinical practice respond to one and not another. The reasons for this finding are still obscure. The conclusions would then seem that if each clinician selects one, two, or three drugs and becomes thoroughly familiar with their activity, he should be able to use chemotherapy effectively in a wide range of psychiatric disorders.

What dosage should be used? Table II lists the neuroleptic drugs in psychiatric use in the United States at the present time and the dosage range recommended for each. These suggested dosages are suitable for the majority of patients, but each case must be considered separately before a decision is reached. Some patients require much less medication, while others may require more than the maximum dosage suggested. As a general rule, the more acute the illness, the higher the dose. (Intramuscular administration of the medication would be recommended under these circumstances.) Usually the more chronic conditions also require a higher dosage. However, as soon as the medication has become effective, dosage should be reduced, if possible. Although there is no dose-weight relationship in prescribing neuroleptics, experience has shown that extremely thin patients should begin with lower doses, since they seem exceedingly prone to the extrapyramidal effect (described below).

How should dosage be increased? Should one (1) begin with a low dose and increase it slowly; (2) use a step-wise progression, with fixed increases at stated intervals; or (3) use a high initial dose, with rapid build-up to tolerance? There has been much de-

bate, but the problem is still unresolved. General experience would seem to favor the step-wise progression.

Because of the frequency with which it is used, a brief description of the technique used in the administration of chlorpromazine therapy is indicated. The intramuscular route may be used for initial treatment in early acute cases, with a dosage ranging from 300 to 400 mg. daily, and changed to the oral form in about 5 days. The oral dose may be increased to 1,000 mg. daily for the chronic psychotic patient. While dosages as high as 4,000 to 10,000 mg. daily have been used in such instances, there is nothing to show that these amounts give results superior to the lower dosage. As a matter of fact, increasing toxicity may be expected (see side effects, below). The treatment should be continued for at least 15 to 30 days for acute patients and 90 days for chronic patients, at which time the case should be reviewed to consider whether treatment ought to be continued or changed.

How long should treatment continue? Careful clinical observation will be the determining factor. If the patient improves on a given dosage after 30 to 60 days of treatment, the drug should be reduced gradually to about one half that amount before consideration is given to separation from the hospital. If there is a recrudescence of symptoms, further treatment is obviously required. The drug should be changed if 30 days of treatment at adequate dosage (as indicated in Table II) yields little result. On the other hand, treatment of a chronic patient (by definition, one who has been ill for more than 2 years) should be continued for at least 90 to 120 days at adequate dosage before reconsideration of the case.

How often are laboratory tests required, and which should be done? A pretreatment complete blood count, alkaline phosphatase, bilirubin, serum glutamic-pyruvic transaminase, serum glutamic-oxalacetic transaminase, as well as isocitric dehydrogenase and urine examinations are recommended. Electrocardiograms and electroencephalograms are of investigational interest but should definitely be done on patients with previous history of cardiac abnormalities or central nervous system disorders. The blood and liver studies should be repeated weekly during the 1st month of treatment, every 2 weeks during the 2nd month, and monthly thereafter until the 6th month. It would not seem probable that drug-induced abnormalities would occur after that time, and, if so, the percentage is so small that it can hardly warrant doing laboratory studies on all patients during the period of treatment and follow-up care.

Will the patient require follow-up medication and, if so, for how long, and at what dose? A flexible approach is recommended:

First psychotic episode with rapid remission within 60 to 90 days. No further medication is required.

Hospitalization for 6 to 12 months. Follow care-

fully for 90 to 120 days with drug treatment at one half the in-hospital dose.

Hospitalization for 1 to 2 years. Follow carefully for at least 1 year with chemotherapy at one half the in-hospital dosage.

Hospitalization for more than 2 years. Indefinite chemotherapy is recommended, during which time one should take pains to ascertain, among other things, whether the medication is being taken regularly.

Patients receiving prolonged treatment should have ophthalmological examinations every 6 months (with slit lamp study), to determine whether any lens or corneal abnormalities (opacities) have appeared, particularly when the dosage exceeds the usual levels.

Is it possible to reduce or discontinue chemotherapy in chronic psychotic patients? The reports are variable. The Veterans Administration Study in 1964 showed that such a treatment policy could not be recommended, although further research would be necessary. Clinical observations indicate that this is a highly individualized matter and cannot be generalized.

Treatment of specific patient categories

In-patients (acute). Use the intramuscular route for rapid control and change to oral medication after 5 to 7 days. Continue treatment at effective levels, reducing dosage to one half about 2 weeks before the patient is discharged.

In-patients (chronic). Administer medication orally at progressively increasing doses until an effective level is reached. (If the patient does not appear to be swallowing the medication, intramuscular medication should be used.) Side effects should be treated whenever necessary (e.g., anti-Parkinson drugs for extrapyramidal reactions), but dosage should be reduced only if the patient does not respond to these corrective agents.

Out-patients. Use one half the in-hospital dose. If the patient works, halogenated phenothiazines may not be indicated, and preference can then be given to the Group III drugs or to thioridazine (Group V) and, eventually, to chlorprothixene (Group VI). The dose may be divided on a b.i.d. schedule, if the patient continues to complain of drowsiness. Eventually, if the dosage is low (e.g., 100 mg. of chlorpromazine daily), it may be taken once at bedtime and thereby help the patient to sleep at the same time. If there is an exacerbation of the illness while the patient is seen in the out-patient service, dosage should be increased rapidly at 3- to 4-day intervals in order to prevent relapse. If this seems imminent, rehospitalization for a brief period with intensive intramuscular medication will abort an incipient psychosis in a majority of patients.

Combined treatment. Psychotherapy, whether group or individual, is strongly indicated when drugs are used. Since psychiatric illness is a global disorder, treatment should be directed toward correcting both the underlying organic substratum and environmental

relationships. A favorable physician-patient relationship will be of inestimable help in long term drug therapy. If any unusual effects develop during treatment, these should be considered in terms of their meaning for the patient.

Different neuroleptics are currently used in combination (e.g., chlorpromazine and trifluoperazine), although the available evidence does not support a practice based on the idea that "if one doesn't work, then two will." Neuroleptics are also being used in combination with "minor tranquilizers." Pharmacologically, the most effective of these "minor tranquilizers" are the muscle relaxant drugs, and they control excessive anxiety which may be part of the illness or may be induced by medication. Occasionally, psychotic anxiety is not effectively reduced by the neuroleptic drugs, and addition of a "minor tranquilizer" can be of considerable help.

Finally, when neuroleptics were introduced, there was much discussion concerning their use in combination with electroconvulsive or insulin coma treatment. Now that insulin coma has been virtually eliminated as a treatment modality, and the use of electroconvulsive treatment has diminished, the problem is virtually nonexistent. However, combined electroconvulsive and neuroleptic therapy may prove useful in the treatment of seriously disturbed refractory patients. Some workers who have adopted this approach omit the drug on the morning of the electric convulsive treatment; others continue dosage throughout the treatment period. For the most part, this procedure is considered safe. Occasional fatalities have been reported, but even here the relationship to drug treatment was not clear.

Contraindications and Precautions

In general, patients who developed prolonged apnea following electric convulsive therapy or protracted coma with insulin coma treatment may also show serious side reactions to the neuroleptics. There are relatively few specific contraindications to the use of neuroleptic drug therapy. These include senile deterioration, with concomitant organic disorder (cardiovascular or pulmonary), depression of the central nervous system, coma, and, of course, previous serious toxic reactions to the neuroleptics. Similarly, precautions are necessary in relatively few cases. A history of hepatic disorder (cirrhosis) is not a contraindication, but liver function tests should be followed carefully by appropriate laboratory examinations (alkaline phosphatase, serum glutamic-oxalacetic transaminase, serum glutamic-pyruvic transaminase, bilirubin, and isocitric dehydrogenase), and dosage guided by the clinical symptomatology. A history of allergy (particularly of the cutaneous variety) requires caution in the administration of neuroleptic drugs, and the patient's exposure to the sun should be limited.

Emphasis must be placed on the relationship of toxicity (e.g., skin pigmentation and lens opacities)

to high dosages of neuroleptic medication over long periods of time. The use of excessive amounts of drugs (e.g., more than 1,000 mg. of chlorpromazine daily; more than 250 mg. of prochlorperazine) over extended periods of time is not advisable. As indicated earlier, prescription of a neuroleptic must be followed by a daily, then weekly, and monthly follow-up over a period of time. While high doses may be used to produce a favorable response within a relatively brief time, the treatment should then be continued with lesser amounts, if this is possible. If the lower dosage is not effective, the drug should be changed.

A history of blood dyscrasia also warrants caution. Serious infectious disorders and severe hypertension represent relative contraindications, and the use of neuroleptics should be determined by the clinical symptomatology. Extreme prudence is advisable in these instances.

With respect to specific drugs, the use of rauwolfia derivatives is contraindicated where there is a history of peptic ulcer, convulsive disorder, or Parkinson's disease.

Side Effects

All unfavorable activity of neuroleptics may be viewed as side effects, being equated with toxicity. Yet, it would seem more constructive to consider them as either physiological or toxic. However, since this can give rise to interminable discussion, the classification proposed herein will refer to organ systems. This would seem more appropriate when one thinks of their pharmacological activity.

Central nervous system findings

Extrapyramidal syndrome. Much debate has centered around whether the extrapyramidal syndrome should be produced or avoided. Earlier studies held that an extrapyramidal reaction was necessary for a favorable clinical result. This was a natural conclusion, based on observations of occasional significant clinical improvement occurring with a neurological syndrome that immobilized the patient. Parenthetically, the psychodynamics of this reaction and possible therapeutic relationships have also been considered. The dilemma is still unsolved, although the present tendency is to view both as dissimilar phenomena, not necessarily related. Yet, the fact remains that only those agents capable of producing an extrapyramidal syndrome are clinically effective, although it is clearly not necessary to produce this effect in each patient.

Symptoms. The extrapyramidal syndrome is comprised of the following symptoms: rigidity, tremor, loss of associated movements, restlessness, cogwheel rigidity, drooling, flexion of the forearms, masklike facies, shuffling gait, and poverty of movement. A neurological syndrome is noted, comprised of dystonia, dyskinesia, oculogyric crises, myoclonic twitching, protrusion of the tongue, opisthotonos, torticollis,

visual disturbances (blurred vision), dysarthria, akathisia, chewing movements of the mouth, and peribuccal tremor.

The incidence of these symptoms varies with the drug used (they are more frequent with the piperazine phenothiazines); the dosage and duration of treatment (more frequent when higher doses are administered for longer periods of time); and the sex of the patient (more frequent in females than males). The neurological symptoms may resemble hysteria in many ways. Torticollis, protrusion of the tongue, and oculogyric crises can be temporarily attenuated by strong positive suggestion.

One syndrome must be recognized immediately to avert a fatal issue. The patient with a severe extrapyramidal reaction begins to perspire profusely, drools, and has respiratory difficulties (dyspnea and cyanosis). The temperature rises, and tachycardia is noted as blood pressure fluctuates. Anxiety increases. Unless treatment is discontinued immediately, the temperature may continue to rise and convulsive seizures will occur. There have been some deaths with a syndrome of this type where treatment was not stopped.

Treatment. The extrapyramidal syndrome may be treated by (1) decreasing the dosage; (2) continuing the same dosage and adding an anti-Parkinson drug; (3) decreasing the dosage and adding an anti-Parkinson drug; or (4) discontinuing the medication (when the reaction appears excessive and does not respond to anti-Parkinson medication).

For serious reactions, use intramuscular medication (e.g., 2 mg. of biperiden methanesulfonate). In order to avoid the potentially annoying effects of anticholinergic compounds, the prescription should provide medication for only 5 days (to be renewed if necessary). However, since some ambulatory patients receiving neuroleptic therapy will require such medication, it would be wise to prescribe the lowest effective dosage. The compounds which are currently available for this purpose are listed in Table III. Of those, biperiden, biperiden methanesulfonate, and procyclidine are considered to be most effective. However, it should be mentioned that some extrapyramidal neurological reactions do not recede rapidly, even when anti-Parkinson medication is used. This has been known to occur in older patients.

Convulsive seizures. These are usually of the grand mal type and are observed early in treatment. In one series, they occurred in a total of 1.1 per cent of the patients treated. Their frequency in epileptic patients showed little or no variation from their incidence prior to neuroleptic medication. There is some evidence, however, that seizures do increase when chlorpromazine is used in patients with a prior history of convulsive disorders.

Treatment. If the patient has a first seizure after beginning neuroleptic medication, an anticonvulsant drug (e.g., diphenylhydantoin, gr. 1.5 t.i.d.) should be

added. If seizures continue, it may be helpful to add chlorthalidopoxide (10 mg., t.i.d.). And, eventually, chlorthalidopoxide can be used to replace diphenylhydantoin. If the seizures do not stop, neuroleptic medication should be discontinued and neurological consultation sought.

If the patient is a known epileptic and seizures become more prevalent with neuroleptic therapy, anticonvulsant medication should be increased, and neuroleptic dosage decreased. Patients who receive piperazine phenothiazines have shown an extremely low incidence of drug-induced seizures, and these drugs may be used, when warranted, to replace the halogenated phenothiazines. The patient should be followed with serial electroencephalograms, although the clinical symptoms should determine the course of action.

Cutaneous disorders. These are more frequent with halogenated phenothiazines, usually appearing as maculopapular-prurigenous reactions on the hands, face, or generalized over areas of the body. However, they may take other forms as well. They are more frequent in females (70 per cent) than in males (30 per cent). The areas which have been exposed to the sun appear to be most vulnerable.

Recently, a cutaneous reaction to high dosage, long term treatment with chlorpromazine and other neuroleptics has been described in which the skin takes a slate grey bluish color, which is sometimes purplish as well. However, in a recent survey of 1,614 patients at Manhattan State Hospital (New York) receiving various neuroleptic drugs over a considerable period of time, this observation was not made. The reaction seems to be almost unknown outside of North America.

Treatment. Usually, the rash can be eliminated by antihistamines, such as tripeleminamine hydrochloride (Pyribenzamine), 25 mg., t.i.d., or steroids, such as hydrocortisone, 5 mg., t.i.d. for 5 days. Contact dermatitis in hospital personnel is best treated by precautionary measures. As indicated below (with reference to the ophthalmological-cutaneous syndrome), the treatment of toxic reactions due to long term medication is still uncertain.

Hepatic findings

Icterus. The incidence is variable in different hospitals, but a generalized survey showed 1.4 per cent. The etiology is still unknown, although allergy has been mentioned. The difference between American (1.4 per cent) and European (0.003 per cent) statistics has never been explained.

Symptoms. The neuroleptics (phenothiazines) can produce a cholangiolitic type of jaundice with biliary obstruction, accompanied by the usual symptoms of such a disorder (nausea, fever, anorexia, abdominal discomfort, malaise, chill, etc.) without evidence of parenchymal involvement.

Treatment. Cessation of neuroleptic medication

TABLE III
Drugs Currently Available for Treatment of
Extrapyramidal Syndrome

Generic Name	Trade Name	Recommended Dosage
		mg., t.i.d.
Benztropine methanesulfonate.....	Cogentin	2
Biperiden.....	Akineton	2
Diphenhydramine.....	Benadryl	25
Ethopropazine.....	Parsidol	50-100
Orphenadrine.....	Disipal	100
Procyclidine.....	Kemadrin	2
Trihexyphenidyl.....	Artane	2

and institution of supportive measures (fluids, adrenocorticotrophic hormone, etc.) is recommended. Prognosis for the immediate illness is good.

Hematological findings

Agranulocytosis. The most serious toxic effect of neuroleptic medication occurs more frequently in females than in males, with a variable incidence of 0.0 per cent to 0.3 per cent with chlorpromazine. There is a lower incidence in Europe. It is extremely infrequent with piperazine side chain compounds but has been noted with promazine, thioridazine, and mepazine.

Symptoms. Agranulocytosis occurs most often during the first 2 months of treatment, unrelated to dosage. The onset is heralded by fever, sore throat, malaise, and weakness. While regular blood counts may demonstrate a progressive leukopenia, the abrupt disappearance of granulocytes can take place within 24 to 48 hours, conceivably, in the interval between two blood counts. Close clinical observation of all patients must be the guide. When patients on neuroleptic therapy develop a fever and complain of sore throat, it is wise to discontinue neuroleptic medication temporarily and, as a precautionary measure, to do a blood count.

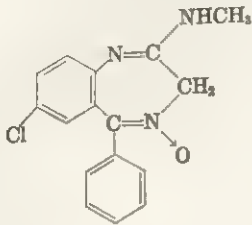

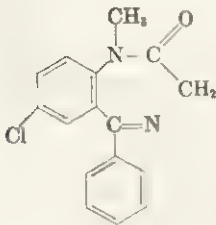

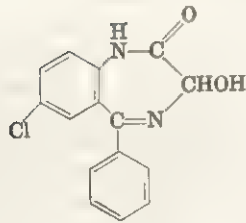

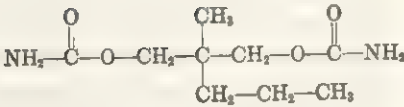

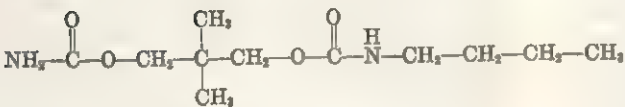

Treatment. A diagnosis of agranulocytosis calls for immediate discontinuation of neuroleptic therapy, medical consultation, and treatment (fluids, transfusions, steroids, and antibiotics).

Ophthalmological findings

Ophthalmological-cutaneous syndrome. Following the description by Greiner and Berry in 1964 of a peculiar slate grey pigmentation found in patients on neuroleptic therapy, concurrent with lens and corneal opacities, additional studies have been published. This syndrome may be found with any of the neuroleptics currently in use in the United States. However, these lesions seem particularly prevalent among patients who have been treated with excessively high doses of different neuroleptics for long periods of time.

Symptoms. The skin has a color which has been variously described as ranging from brown to bronze, grey, purplish grey, or an admixture of grey and brown. Eye examination with a slit lamp showed lens

TABLE IV
Chemical Structure of Non-neuroleptic Drugs

Chemical Structure	Generic Name	Trade Name
	Chlordiazepoxide	Librium
	Diazepam	Valium
	Oxazepam	Serax
	Meprobamate	Miltown, Equanil
	Tybamate	Solacen

and corneal opacities, although visual acuity was unimpaired.

Treatment. Treatment is primarily preventive. In cases where the clinical condition requires long term treatment, dosage must be reviewed constantly and kept to a minimum. The possibility of intermittent medication should also be considered. Since, as mentioned above, the lesions can be produced by any of the available drugs, it would be pointless to change from one compound to another. Perhaps Brill et al. have stated the case most succinctly: "The tenor of all expert advice—whether from ophthalmologists or psychiatrists—is that treatment should be continued when it is psychiatrically indicated." The use of chelating agents has been suggested, but the number of patients so treated is still too small to form an opinion.

Side effects in out-patients. The great majority

of physiological or toxic effects described above usually do not occur in nonhospitalized patients to any significant extent, for two reasons. First, this patient population receives relatively low dosages of neuroleptic drugs. Second, they have usually been hospitalized for varying periods of time when these symptoms would have occurred.

Certain recommended procedures which were outlined earlier in connection with the medical evaluation of patients on neuroleptic therapy warrant repetition in this context. Should repeated blood counts and liver studies be done on nonhospitalized patients? Unless there is a medical reason (history of blood dyscrasia, etc.), this would not seem necessary. May a patient with a history of alcoholism or cirrhosis be treated with neuroleptics on an out-patient basis? Yes, provided the dosage is kept within reasonable limits. However, liver function should be determined

approximately every 3 months and include an alkaline phosphatase, isocitric dehydrogenase, and serum glutamic-oxalacetic and -pyruvic transaminase. Finally, a question which is raised consistently concerning the long term use of neuroleptics, either within the hospital or on an out-patient basis, concerns their addictive qualities. These phenomena can be considered almost nonexistent.

Non-neuroleptic Drugs

These drugs, which are also called "minor tranquilizers," are distinguished from the neuroleptics by their chemical structure (Table IV), pharmacology, indications, and side effects. They are used primarily in office psychiatric practice and as an adjunct to neuroleptic medication in the hospital. However, it should be emphasized that it is *not* probable that "patients who respond to treatment with the minor tranquilizers also will usually respond to properly selected doses of the classic sedatives" (*New Drugs*, 1965). Clinical study has shown that the muscle-relaxing effects of the chlordiazepoxide-diazepam-meprobamate group are not a property of barbiturates, and the kind of relaxation these newer drugs offer for the extremely anxious psychoneurotic is not apparent with the classic sedatives.

The drugs in this group should be used judiciously, in appropriate doses, with concomitant psychotherapy. By reducing anxiety, they can facilitate the psychotherapeutic process. The addiction-prone individual should be treated with circumspection, for, in contrast to the neuroleptics, some of the "minor tranquilizers" do have addicting qualities, *on extremely rare occasions*. Although these agents are used primarily in the treatment of neuroses, their effectiveness has not been demonstrated. At best, they sedate the patient; they have no effect on the psychotic symptoms.

Indications. The non-neuroleptic drugs have been recommended for the treatment of tension; anxiety; reactive depression; psychosomatic disorders; insomnia (by itself or concomitant with other symptoms); agitation, restlessness, and excitability; marked irritability; senile agitated states; chronic brain syndrome (when used in conjunction with the neuroleptics); acute alcoholism; convulsive disorders (chlordiazepoxide); acute muscle spasm; and musculo-skeletal disorders.

Treatment procedure. Non-neuroleptic drugs in current psychiatric use in the United States and their recommended average daily dose are listed in Table V. Of this group, chlordiazepoxide, diazepam, and meprobamate are the most widely used and the most effective. However, the evidence for tybamate is promising, and further studies on oxazepam are required before any definite statements can be made. (The latter compound will undoubtedly prove effective, since it is so similar in structure to the chlordiazepoxide-diazepam group.)

Specific procedures. The specific procedure rec-

TABLE V
Non-neuroleptic Drugs in Current Psychiatric Use

Generic Name	Trade Name	Dosage per os.
		mg., t.i.d.

Tybamate.....	Solacen	700-1,400

ommended in the administration of the non-neuroleptic drugs which are used most widely (i.e., chlordiazepoxide, diazepam, and meprobamate) is outlined below.

Chlordiazepoxide. Begin treatment with 5 mg., t.i.d., and increase by 5-mg. increments. After reaching total effective levels (about 30 mg.), establish a lower maintenance dose.

Diazepam. Begin treatment with 2 to 5 mg., t.i.d. After reaching total maximum dosage (about 30 mg.), decrease for maintenance.

Meprobamate. Begin treatment with 400 mg., t.i.d., or q.i.d., for 1 week. Increase by 400-mg. increments per week until clinical effect is noted or bothersome side effects appear.

Contraindications and precautions

General considerations. There are no absolute contraindications for the use of the "minor tranquilizers," except for patients with a known history of adverse reactions. However, caution should be exercised in certain instances. (1) Drowsiness or ataxia which may affect job performance or other activities, e.g., driving an automobile, may be avoided by close clinical supervision and slow increase of dosage. (2) *Great care should be exercised in prescribing for addiction-prone patients.* Those with a history of alcoholism should be followed closely. If the dose is high and the period of treatment long, withdrawal from medication should be gradual in the latter group. (3) Patients with a history of allergies or hepatic disorder should be followed closely.

Specific side effects. Apart from drowsiness and hypotension, most of the reactions attributed to the non-neuroleptic drugs are undoubtedly toxic in nature. The following have been reported: drowsiness, apathy, ataxia, giddiness, lethargy, syncope, hypotension, skin rash, nausea, headache, paradoxical anxiety and rage (in disturbed schizophrenic pa-

tients), vomiting, rash, chills, fever, rare blood dyscrasias, withdrawal reaction with convulsions following abrupt termination (associated with chlordiazepoxide and meprobamate), jaundice, and agranulocytosis.

Treatment. Most of the reactions can be handled by judicious attention to dosage. Drowsiness, apathy, ataxia, giddiness, lethargy, and syncope require a reduction in dose. If paradoxical anxiety and rage develop, in all likelihood the drug cannot be given further. The same applies to blood dyscrasias, jaundice, and agranulocytosis as well, although these reactions are *extremely rare* in any case. Withdrawal phenomena should be anticipated in addiction-prone patients and/or those who have received very high dosages. In such cases, the dose should always be decreased by the same increment and over the same period of time that was used for the build-up.

General comments. The use of compounds in this group has received an inordinate amount of attention, with far too much emphasis upon their toxic effects. This would appear unwarranted, in view of the benefits derived by patients. There is nothing to indicate that they decrease anxiety and induce euphoria to a point of producing an artificial "nirvana." In the usual dosage range, chlordiazepoxide and meprobamate do not produce addiction. It is the unusual patient, with a history of drug dependency, who is most prone to this reaction. If one considers the small number of such cases in the literature in relation to the tremendous number of patients taking these compounds throughout the world, addiction can be considered truly a rare possibility. Interestingly, European authors have given this problem very little attention.

In brief, careful selection of one of these non-neuroleptic drugs; accurate dosage; careful attention to complaints of a physiological or toxic nature; interpretation of such complaints within a proper frame of reference; and, when necessary, discontinuation of the medication will enable the patient to achieve maximum benefit from treatment.

Suggested Cross References

For a comparison of pharmacotherapy with other forms of organic treatment, see Kalinowsky's sections on the organic therapies (Sections 35.6, 35.7, and 35.8). For a discussion of fundamental concepts of psychopharmacology see Section 2.3 by Harold Himwich, in Area B on basic sciences. In addition, the chapters on the various specific clinical syndromes contain references to the use of psychotropic drugs in the treatment of these conditions.

Treatment Summary

Neuroleptic Drugs (Major Tranquilizers) in Current Psychiatric Use in the United States (The reader is referred to Table II for a list of these drugs.)

Indications. Acute and chronic psychoses (schizophrenic, manic, involutional, and senile); agitated depression; acute al-

coholic and episodic psychoses; organic brain disorder and psychoses due to mental deficiency; "borderline states"; childhood schizophrenia.

Contraindications. Cardiovascular or pulmonary disorders (the seriousness of the psychiatric disorder must be weighed against the organic disease), coma, active hepatic parenchymal inflammation, blood dyscrasia, severe hypertension or hypotension, previous severe reaction to neuroleptics.

Side effects of neuroleptic drugs

Psychological. Paradoxical anxiety, marked passivity and asthenia, insomnia, depersonalization, increased dreaming and/or nightmares, confusional states, aggravation of the psychosis.

Central nervous system. Extrapyramidal syndrome: tremor, rigidity, cogwheel phenomena, disturbance in associated movements, disturbance of gait, akathisia, akinesia, hyperkinesia; dyskinesia, hypotonia, myoclonic twitching, oculogyric crises, perioral spasms, protrusion of the tongue, restlessness, apathy, weakness, convulsive seizures, opisthotonos, and diplopia.

Cardiovascular. Hypotension, hypertension, tachycardia, syncope, thromboses, peripheral edema.

Hematological. Leukopenia, leukocytosis, agranulocytosis, thrombocytopenia, purpura, eosinophilia, anemia.

Hepatic. Jaundice (cholelithic).

Gastrointestinal. Dryness of the mouth, drooling, pyrosis, nausea, vomiting, diarrhea, constipation, increased appetite.

Skin. Erythema, urticaria, eczema, contact dermatitis, toxic-allergic reaction, petechia, abnormal pigmentation.

Endocrinological. Changes in menstrual cycle (amenorrhea, menorrhagia), lactation, breast engorgement, weight gain, altered libidinal drive (inhibition of ejaculation, impotence).

Ophthalmological. Lenticular and/or corneal opacities, conjunctivitis, retinitis pigmentosa, blurred vision.

Rauwolfia compounds (The reader is referred to Table II for a list of these drugs.)

Indications. Acute schizophrenic or manic psychoses, chronic schizophrenia, delirium tremens, senile agitated states.

Contraindications. Gastric or duodenal ulcer, depression, history of attempted suicide, epilepsy, organic confusional states, asthenia, fatigue, Parkinson's disease or extrapyramidal reaction, and postencephalitic disorders.

Side effects. Extrapyramidal reaction, convulsions, drooling, nasal congestion, peripheral edema, bradycardia, hypotension, increased appetite, weight gain, gastric hyperacidity, diarrhea, lactation, menstrual disturbances, incontinence, depression, cutaneous flushing, rash, and purpura.

Non-neuroleptic Drugs (Minor Tranquilizers) in Current Psychiatric Use in the United States (The reader is referred to Table V for a list of these drugs.)

Indications. Tension, anxiety, acute alcoholism, hysteria, or panic states, insomnia, agitation, restlessness, marked irritability, senile agitation, chronic brain syndrome, acute muscle spasm or musculoskeletal disorders, psychosomatic disorders, convulsive disorders. (These drugs are also useful as an adjunct to psychotherapy or in combination with neuroleptic therapy.)

Side effects

Psychological. Addiction, apathy, paradoxical rage, euphoria.

Central nervous system. Headache, slurred speech, ataxia, drowsiness, lethargy, somnolence, giddiness, muscular incoordination and/or tremor, withdrawal reaction with convulsions.

Cardiovascular. Hypotension, syncope.

Hematological. Thrombocytopenic purpura, anemia, leukopenia, agranulocytosis.

Gastrointestinal. Nausea, vomiting, constipation, or diarrhea.

Hepatic. Jaundice.

Skin. Rash, urticaria.

Endocrinological. Menstrual irregularities, altered libido.

Miscellaneous. Chills, fever, angioneurotic edema.

Precautions. Precaution should be exercised with patients who show drowsiness or ataxia following medication; who are addicts or "addiction-prone"; or who have a history of alcoholism, epilepsy, allergy, hepatic disorder, or blood dyscrasia.

amine oxidase inhibitors—in the late 1950's and their subsequent therapeutic use justify a careful and thoughtful appraisal of the various clinical studies available to date on the effectiveness of these drugs.

History. The way the antidepressant drugs were discovered has important implications for the practitioner. Imipramine was developed in the course of a search for a better chlorpromazine-like drug. More specifically, Kuhn (a Swiss clinical investigator), in evaluating the antipsychotic activity of imipramine, found that, while it was ineffective in schizophrenics, it did benefit depressed patients. Iproniazid, the first of the monoamine oxidase (MAO) inhibitors, was used initially in the treatment of tuberculosis and was found to cause euphoria, and even elation, in tubercular patients. Subsequently, it was also used successfully to reverse reserpine-induced sedation in animals. Both Crane and Kline, working independently, administered the drug to depressed patients with favorable results.

Pharmacological activity. Once these two active antidepressant drugs had been developed, the pharmaceutical industry proceeded, on the basis of various animal tests, to develop several additional drugs, which resemble either imipramine or iproniazid in their pharmacological properties. However, relationships between chemical structure and pharmacological activity which have evolved from animal test systems do not necessarily parallel structural correlates of antidepressant activity in man. It was for this reason, perhaps, that the antipsychotic property of the phenothiazines was not predicted by basic pharmacological research, but was observed first by clinicians. The history of the development of both the antidepressant and the antipsychotic drugs points up the fact that major scientific discoveries can, on occasion, evolve as a concomitant of clinical practice or investigation, rather than as deductions from basic animal research.

In addition, it is important to note that the fact that the antidepressant drugs often do not influence the normal organism (in a base line state) does not preclude their ability to correct an abnormal condition. For example, aspirin reduces "abnormal" hyperpyrexia but does not lower temperature in the normal organism. Amphetamine is a euphoriant and a stimulant, but it is not an antidepressant, in the precise sense of the word. In contrast, the imipramine-type drugs and the MAO inhibitors are antidepressants, not general euphoriants or stimulants. Thus, while imipramine has a marked antidepressant action on depressed psychiatric patients, there is good evidence that it has little euphoriant action on normals. The evidence is less clear with the MAO inhibitors, since the reaction of normals to these drugs has not been well studied. It is known, however, that when the MAO inhibitors are used for the treatment of hypertension, most patients do not note any marked mental effect, although a few are sedated and others experi-

35.2 ANTIDEPRESSANT DRUGS

ence a euphoriant effect with insomnia. The latter reaction may not be identical with the antidepressant effect, but definitive evidence is not yet available on this point.

This section will discuss the specific attributes of the drugs in these classes which are currently in general prescription use, as listed in Table I. In addition, however, since new compounds with radically different properties may be discovered by chance or design in the near future, some general principles of drug therapy and clinical pharmacology will be stressed as well.

General considerations. Inevitably, selecting the most effective antidepressant drug for the treatment of the individual patient and supervising its subsequent clinical administration will raise a number of questions.

Indications. In what kinds of depressive conditions is the drug particularly useful? Since antidepressant drugs are currently used to treat affective depression occurring in almost any clinical context, it is important to make the following distinction. Is the drug to be administered to patients who are depressed over a medical illness; to patients with permanent personality disorders and transient depressive symptoms; to those in acute reactive depression; to persons in agitated or retarded endogenous depression; to schizophrenics in order to counteract depression; or to patients with anergia, excessive fatigue, or hypochondriasis in the hope that these symptoms may be "depressive equivalents"?

Side effects. What side effects are typically associated with the normal use of the drug? Should the patient be warned about these beforehand? Does the drug adversely affect existing medical conditions? Under what conditions should it be administered in combination with other drugs? Does it cause unusual or severe side effects when combined intentionally, or unintentionally, with other drugs or foods? Should the patient be warned to avoid certain drugs or foods? Could the patient commit suicide successfully with the drug? What is the prescribed treatment in the event of an overdose?

Clinical effects. Is the drug short-acting (making frequent administration important), or long-acting? Are there cumulative effects? Does effective administration require high, loading doses, followed by lower maintenance doses? How can drug treatment best be combined with psychotherapy?

How rapidly does the drug produce clinical change? Both the MAO inhibitors and the imipramine-like drugs may produce some change in the patient within the 1st week; but improvement may be delayed for 2 weeks or more, and it may take a month before the patient derives full benefits from the drug. Such factors have obvious clinical implications: they will determine what the patient should be told, how frequently he should be seen, and the point at which the psychiatrist decides that a certain patient is not

going to respond to a particular drug. Finally, the psychiatrist is understandably concerned with the effectiveness of the specific antidepressant drug he has selected in comparison with inert placebo or nondrug treatment, another antidepressant drug, or electroconvulsive therapy, in terms of speed of action, overall efficacy, and safety.

This section will attempt to answer some of these questions. In addition, appropriate ways of operating in situations where only partial knowledge is available will be suggested. In general, however, the questions which are asked with regard to "new" treatment procedures should be raised in relation to "old" treatment methods as well.

Over-all evaluation of antidepressant therapy

Methodological issues. A key issue in any study of the efficacy of a new antidepressant drug is the general efficacy of the drug in comparison with other treatment methods. Here, controlled clinical trials comparing the new drug with the effects of inert placebo, electroconvulsive therapy (ECT), or a well studied antidepressant, such as imipramine, are usually most revealing. For example, in a recently reported study, approximately 30 per cent of the depressed patients who received placebos showed substantial spontaneous improvement. This figure encompasses, in unknown proportions, patients who improved spontaneously for various internal or external reasons; patients who responded to the nondrug aspects of their treatment; as well as an unknown proportion of true placebo responders, i.e., those patients who get better only because they are receiving a dummy tablet from a physician.

Uncontrolled studies of new psychoactive drugs almost always yield a much higher reported improvement rate than do controlled studies. In part, this may be a result of the bias of the clinical investigator, who sees more improvement than is really there because of his strong wish to find a good new drug. Since current drugs often take 1 to 3 weeks to act, a new antidepressant which acts in 1 or 2 days would be an important addition to drug therapy, even if its over-all efficacy were no greater than that of existing drugs. On the other hand, it should also be pointed out that the highly skeptical approach which characterizes some controlled double blind studies may reduce the actual rate of improvement occurring in the patients under investigation.

Experimental group. Probably the most crucial factors in studies of the efficacy of the antidepressant drugs are the composition of the patient sample treated and identification of the type of patient who responds to a given drug. For understandable reasons, controlled studies which not only report global judgments of degree of improvement but also describe in detail changes in various aspects of the depressive psychopathology of the patients studied (e.g., retarda-

tion, agitation, guilt, and anxiety) are particularly useful.

Again, since some types of patients (e.g., schizophrenics, patients with chronic character disorders, or paranoid patients with depression) may not respond dramatically to antidepressant drugs alone, the ineffectiveness of a drug in a reported controlled study may be a function of the proportion of such poor responders in the patient sample. Similarly, indication of the proportion of patients, if any, who are made worse by use of the drug has important clinical and research implications. Clinical studies must also allow for patients who are receiving combined drug treatment; since other agents, such as the phenothiazines, may themselves have some efficacy in relieving symptoms in depression, the results obtained from studies of such patient groups cannot be interpreted as fully supporting the value of the antidepressant drug.

Control group. A similar problem arises when an active drug (amphetamine or atropine, for example) is used as the comparison treatment in a controlled study. Such an agent may either make depressed patients worse or better; therefore, it provides a different basis for comparison than does an inert placebo or a standard antidepressant drug.

Evaluation of side effects. Identification of the side effects caused by antidepressant drugs constitutes another methodological problem in the evaluation of these agents. In fact, many of the common side effects listed for almost all the antidepressant drugs (e.g., fatigue, dry mouth, dizziness, constipation, profuse sweating, tremor, nausea and vomiting, drowsiness, insomnia, and sexual impotence) are fairly typical symptoms of the depression itself. Some, or all, of these symptoms may have been present prior to treatment with the drug, and others may emerge spontaneously during treatment without actually being caused by the drug. The use of control groups receiving placebos is, therefore, every bit as important in interpreting the possible relationship of side effects to antidepressant medication as it is in evaluating the relationship between the use of the drug and observed clinical improvement.

In addition, a reference standard may facilitate interpretation of the degree of risk attributable to antidepressant drugs which may be associated with rare, but severe, side effects. More specifically, unless definitive evidence is available, it is necessary to show that the frequency with which a given side effect occurs in conjunction with administration of the drug is greater than its base rate occurrence in a comparable untreated population. Unfortunately, however, in the absence of sound data, the clinician will frequently have to evaluate the degree of risk himself. Theoretically, the Food and Drug Administration has the responsibility for reviewing information of this sort and deciding whether a drug should be removed from the market or its label changed, but in the case of a

moderately effective drug which produces severe side effects only rarely the clinician will often be asked to use his own judgment as to whether the possibility that the drug may benefit a given patient outweighs the possibility of a serious toxic effect. In any event, the current and future literature on antidepressant drugs should be read carefully with these methodological issues in mind.

Imipramine-Type Drugs

Definition. Imipramine (iminodibenzyl) derivatives and amitriptyline (cycloheptadiene) derivatives are similar to the phenothiazine derivatives in structure. The desmethyl derivatives of imipramine and amitriptyline, specifically, desmethylimipramine (desipramine) and desmethyلامitriptyline (nortriptyline), appear to be active antidepressants. These drugs are readily absorbed from the gastrointestinal tract. In humans, imipramine and amitriptyline are partially metabolized to their desmethyl derivative. Amitriptyline is said to be more sedative than imipramine; the desmethyl derivatives are said to be less sedative.

Clinical effects. In normal individuals, imipramine and amitriptyline produce little effect other than slight sedation. However, in severely depressed psychotic patients they produce a striking improvement in behavior and a marked lessening of depression, generally within 3 to 10 days after the onset of treatment. Consequently, patients who do not respond after receiving an adequate dose of these drugs for a 3-week period probably will not respond at all. Furthermore, the degree of response in the first 3 weeks of treatment predicts the ultimate therapeutic response.

Imipramine

Results of treatment. Table II lists the number of double blind studies in which imipramine was shown to be more effective than placebos, as opposed to the number of studies in which imipramine was equal to placebos in therapeutic effectiveness. These statistics indicate that most of the studies reported demonstrated the therapeutic effectiveness of imipramine. However, for the most part, those studies which failed to show a positive effect either used a small patient sample, or small doses of the drug. On the other hand, however, two of the studies which did not show a clear cut imipramine effect did use reasonably large samples. Perhaps the relative ineffectiveness of imipramine in these studies may be attributed to the clinical characteristics of the patient sample, which included a fair number of schizoaffective patients, elderly patients, and patients with compensation neuroses.

More specifically, Klerman and Cole, who compiled the statistics for the therapeutic success (versus the relative lack of success) of imipramine, found that 65 per cent of the 550 patients treated with imipramine

improved, while only 31 per cent of the 459 patients who received placebos improved. Furthermore, the percentage of patients who responded to placebo differed in different treatment settings, so that the response was greater among the population seen on acute in-patient services (46 per cent), than on either the chronic in-patient services (16 per cent) or the out-patient services (21 per cent). However, the percentage of patients responding to imipramine was greater in all three settings. Although these data clearly indicate that imipramine is superior to placebo, they have other important implications as well: one-third of the patients treated with imipramine did not show even moderate improvement, which certainly indicates the need for an improvement in treatment methods.

Only a few recent studies make any real claim to have identified a group of patients for whom imipramine has proven particularly effective. Kiloh performed a discriminant function analysis in patients treated with imipramine and concluded that the variables which were associated with a good drug response were those indicative of endogenous depression, e.g., depression different in quality from normal states of sadness; feelings of severe guilt and unworthiness, and severe retardation or agitation; and depressions accompanied by such symptoms as early morning awakening and weight loss. On the other hand, patients with neurotic depressions, whose premorbid personalities showed hysterical, irritable, and hypochondriacal features, along with self-pity, did not demonstrate a clear cut favorable response to the drug. On another level, Klerman and Cole's review of the literature suggests that studies of imipramine carried out in out-patient treatment settings show a more striking drug-placebo difference in improvement rates (50 per cent) than do studies carried out on newly admitted in-patients (16 per cent). Thus, there may be several subpopulations of drug responders.

Donald Klein recently described a quite different group of patients who respond uniquely both to imipramine and to MAO inhibitors. These patients are not depressed but show phobic symptoms associated with recurrent severe anxiety attacks. These symptoms are unresponsive to any of the existing tranquilizers but respond dramatically to imipramine. Since these patients respond to antidepressant drug treatment, some investigators would regard these as cases of "masked" or atypical depression. However, it is equally possible that these patients have a non-depressive psychiatric condition, which, nevertheless, is uniquely responsive to "antidepressant" drugs.

Paranoid patients often do poorly with imipramine and, to a lesser extent, with amitriptyline. Wittenborn has found, too, that premenopausal patients, with a self-critical premorbid personality, tend not to do well with imipramine. However, in general, attempts to identify drug-susceptible populations, as

opposed to those populations whose response is negligible, have not been sufficiently exhaustive. Nor have the studies described above been cross-validated. Thus, it is apparent that the matching of clinical subtypes of depression to effective treatment by a specific drug must await further research.

Dosage. Dosage is a particularly important variable in the treatment of depression with drugs. As mentioned earlier, some of the trials which showed less striking results undoubtedly reflected the low doses used. Many psychiatrists favor dose levels of 200 to 250 mg. of imipramine-type drugs a day, a level which should be obtained gradually over a period of several days. Other investigators feel that the ideal therapeutic dose lies between 150 and 350 mg. per day. However, clinical evidence would seem to indicate that, with many patients, increasing the dose above 250 mg. does not produce greater improvement, although it does produce more intense side effects.

Furthermore, as indicated above, while the drug may have an effect within 3 days after the onset of

treatment, it may take as long as 3 weeks before there is any evidence of improvement. Therefore, if the patient receives a low dosage of imipramine for 20 days and then, on the 21st day, receives a higher dosage, this could not be considered an adequate therapeutic trial. Since the higher dose was administered for only 1 day, he may not have received a therapeutic dosage over a long enough period of time to benefit from the antidepressant effects of the drug. As is true of most areas of psychopharmacology, unfortunately, dose-response curves for the antidepressant drugs have not yet been determined in human beings, although it is hoped that future research will remedy this defect. In the meantime, one such study has been conducted in which the investigators concluded that there was little therapeutic effect with doses of approximately 150 mg., but that higher doses, such as 240 mg. a day, did evoke a therapeutic effect.

Amitriptyline

Results of treatment. It can be seen from Table II that amitriptyline is equal to, or perhaps slightly more effective than, imipramine in antidepressant activity. However, since two of the three studies which demonstrate the greater effectiveness of amitriptyline were done by the same authors, the superiority of this antidepressant drug requires confirmation by other investigators. Nevertheless, on the basis of studies done to date, amitriptyline has proven more effective, more often, in the treatment of more severely depressed patients, particularly older women. In a single study, amitriptyline also proved slightly faster-acting than imipramine, although this finding also requires further confirmation.

Dosage. The effective dose for amitriptyline is comparable to that for imipramine (150 to 250 mg. per day).

Desmethyl derivatives

Definition. The desmethyl derivatives of imipramine and amitriptyline, namely, desipramine and nortriptyline, are similar in many pharmacological parameters to the parent compounds but appear to be more stimulating and may aggravate anxiety and tension. Their optimal dosage ranges have not yet been definitely established. Although these compounds were both more potent (less drug being required to obtain the same effect) and faster-acting in animals, in humans the required dose and the speed of action appear to be quite similar to those of imipramine and amitriptyline.

Results of treatment. Preliminary clinical evidence indicates that the desmethyl derivatives are more effective in the treatment of retarded depression. On the other hand, desipramine showed no superiority over placebo in a study of depressed Veterans Administration patients, a group which might be expected to include schizo-affective psychoses and compensation neuroses with depression. In one trial comparing imi-

pramine with desipramine, both were found to have an equal therapeutic effect. However, in another trial, desipramine was found to be less effective than imipramine. Nortriptyline has appeared to be an effective antidepressant in preliminary studies, which included samples of chronically ill geriatric patients.

Side Effects of Imipramine and Amitriptyline

Autonomic effects. The side effects of amitriptyline and imipramine are practically identical. Both drugs can cause the typical autonomic effects expected as a result of their anticholinergic pharmacological properties, such as dry mouth, palpitations, tachycardia, loss of accommodation, postural hypotension, fainting, dizziness, vomiting, constipation, edema, and aggravation of glaucoma. In rare instances, urinary retention and paralytic ileus have also been observed. Both of these side effects, however infrequent, can lead to serious or even fatal complications, particularly if imipramine or amitriptyline has been combined with other drugs having similar anticholinergic effects, e.g., a phenothiazine with an anti-parkinsonian drug. Other rare side effects include galactorrhea, edema, and profuse sweating. In general, dry mouth is the most noteworthy of the autonomic side effects, and patients should be warned that it may occur. Postural hypotension is not usually a problem. In those rare instances where it is troublesome, some authors advise the use of α -fluorohydrocortisone (0.025 to 0.05 mg. b.i.d.). (In summary, on the whole, autonomic side effects are very mild and tend to become even less troublesome after the first few weeks of treatment; in any event, they can be controlled by adjusting the dosage of the drug.)

Allergic and hypersensitivity effects. Skin reactions are noted early in therapy and often subside with reduced dosage. Jaundice, which occurs rarely, is of the cholestatic type, similar to that attributed to chlorpromazine. With desipramine, imipramine, and amitriptyline, jaundice usually occurs in the first few months of treatment, following inconstant prodromal symptoms of abdominal pain, fever, and anorexia. However, it generally recedes rapidly after treatment is discontinued. (Liver function tests show no clear cut alteration with imipramine treatment.) Agranulocytosis is a rare complication of imipramine and has been reported in approximately 12 cases, which included 3 fatalities. Agranulocytosis has also been reported to be associated with amitriptyline treatment in one instance. Finally, rare cases of leukocytosis, leukopenia, and eosinophilia have been observed with imipramine and amitriptyline.

Cardiovascular effects. When administered in usual therapeutic doses, both imipramine and amitriptyline may cause flattened T waves, prolonged QT intervals, and depressed S-T segments in the electrocardiogram. Cardiovascular incidents have occurred in the elderly. However, once again, it should be emphasized that sometimes it is difficult to separate

a side effect which is causally related to a drug from a cardiovascular incident which is precipitated by other factors but, by chance, coincides with drug therapy. This is particularly true with elderly people. Since cardiovascular disease is common among this segment of the patient population, it is difficult to ascertain whether such incidents should be attributed to drug treatment.

Central nervous system effects. Imipramine and amitriptyline may cause a persistent, fine, rapid tremor, particularly in the upper extremities, but also in the tongue. Twitching, convulsions, dysarthria, paresthesia, peroneal palsies, and ataxia may occur in rare instances. Disturbance of motor function is likely to occur in elderly patients and may have serious consequences. Insomnia has also been noted in elderly patients on occasion, but it is transitory and responds well to nightly sedation. From time to time, both amitriptyline and imipramine may cause an episode of hypomanic or schizophrenic excitement. It is important to note that such episodes usually occur in patients with schizophrenia, mental deficiency, or chronic brain syndrome, rather than neuroses, which suggests that a preexisting substrata of disease must be present for the drug to exert its psychotomimetic properties. Such symptoms usually subside within 1 or 2 days after withdrawal of the drug and can be controlled by administration of the phenothiazine derivatives. Finally, withdrawal reactions have been observed on abrupt termination of imipramine, after 2 months of treatment with 300 mg. daily. However, these reactions were mild, consisting of nausea, vomiting, and malaise. In any event, since a gradual reduction in dosage is usually carried out in preference to abrupt withdrawal, this should not pose a clinical problem.

Monoamine Oxidase Inhibitors

Definition. Iproniazid, the first widely prescribed monoamine oxidase inhibitor, produced troublesome liver toxicity. This led to the synthesis of the other hydrazine antidepressants (isocarboxazid, nialamide, and phenelzine), and the nonhydrazine monoamine oxidase inhibitors (tranylcypromine and pargyline).

Results of treatment. Table II lists the number of controlled studies showing the efficacy of these drugs versus that of a placebo. Comparisons with imipramine are also presented; since imipramine constitutes the best studied and most widely used alternate chemotherapy for depressed patients, it provides a good standard with which to compare the MAO inhibitors. It can be seen from these statistical data that the therapeutic effect of tranylcypromine is greater than that of placebo. There is evidence, in two well controlled studies, that iproniazid is also therapeutically effective.

Phenelzine was found to be slightly more effective than isocarboxazid, and tranylcypromine was found to be slightly more effective than pargyline. In terms of

over-all comparison, phenelzine and isocarboxazid were shown to be effective antidepressants in some studies; however, other studies have failed to substantiate this finding. Similarly, in general, nialamide, in usual doses, has not been found effective as an antidepressant; but it was shown to be effective in one study, in which it was used in high doses.

In general, on the basis of the evidence, one might classify the MAO inhibitors in terms of their clinical effectiveness as follows: tranylcypromine and iproniazid appear to be most effective, nialamide and isocarboxazid are least effective, and phenelzine occupies a position somewhere in the middle. Roughly speaking, reported toxicity parallels clinical effectiveness. This raises a question as to whether some MAO inhibitors are less toxic at dosages recommended by the manufacturer because these induce less monoamine oxidase inhibition and, concomitantly, whether their diminished pharmacological effect also diminishes their therapeutic effectiveness.

In fact, the therapeutic effect of the monoamine oxidase inhibitors may well be mediated through their monoamine oxidase-inhibiting property. However, very few studies of humans have established a definitive relationship of therapeutic effects to the degree of monoamine oxidase inhibition. On the whole, such studies yield mixed results: some show a relationship; others do not. In addition, dose-response studies, which might clarify the situation to some extent, have not been done with this class of drugs.

Side effects

Toxic effects. As mentioned earlier, initially a number of cases of severe hepatic necrosis with a high fatality rate (about 25 per cent) were reported with iproniazid, which led to its withdrawal from general prescription use. Currently, the incidence has been estimated as ranging from 1 in 3,000 to 1 in 10,000 patients. Generally, the illness occurs anywhere from a few days to 6 or more months after the onset of drug treatment. Hepatocellular damage has also been reported in patients treated with other hydrazine MAO inhibitor antidepressants, i.e., phenelzine, nialamide, and isocarboxazid. However, while definitive studies of the incidence of these reactions have not been made, it is felt that they occur less frequently with these MAO inhibitors than with iproniazid. Investigators have also reported that a patient placed on a second trial of MAO inhibitors can have a recurrence of jaundice, whether the same or a different MAO inhibitor is administered. Consequently, the free hydrazine, rather than the MAO-inhibiting property, is suspected as the causative agent. (Jaundice is not reported with nonhydrazine MAO inhibitors.)

Autonomic side effects. The MAO inhibitors cause autonomic (anticholinergic) side effects such as dry mouth, dizziness, orthostatic hypotension, epi-

gastric distress, constipation, delayed micturition, delayed ejaculation, and impotence.

A side effect of special importance which may result from the use of the MAO inhibitors, particularly tranylecypromine, is the hypertensive crisis which is occasionally accompanied by intracranial bleeding. Severe occipital headache, stiff neck, sweating, nausea and vomiting, and sharply elevated blood pressure are common prodromal symptoms. It has been estimated that 1 death per 100,000 has occurred following such crises in patients treated with tranylecypromine. In many instances, these reactions were observed to follow the ingestion of well ripened cheeses, such as Camembert, Liederkranz, Edam, or cheddar, which contained appreciable amounts of tyramine. Apparently, the pressor effects of tyramine are potentiated because it is protected from destruction by the MAO inhibition. Similar attacks might be triggered by alcohol, epinephrine, cocaine, broad (fava) beans, Marmite, Bovril, yogurt, amphetamine, ephedrine and other sympathomimetic agents, beers, wine, creams, histamine, and bee venom. Furthermore, the above complications can also occur with other MAO inhibitors, including phenelzine, nialamide, and pargyline. However, the possibility of such side effects as headache, hypertensive crisis, and intracranial bleeding can be reduced by careful attention to diet and by avoidance of pressor drugs or related substances. Patients should be appropriately warned. Should these side effects occur despite such precautions, they can be treated by the administration of phentolamine.

The combination of an MAO inhibitor with an imipramine-type drug can lead to a syndrome characterized by restlessness, dizziness, tremulousness, muscle twitching, sweating, convulsions, hyperpyrexia (104° to 109°), and sometimes death. These reactions can also occur when an MAO inhibitor is replaced by an imipramine-type drug. Consequently, a wash-out period of 7 to 10 days is recommended before such a substitution is made. Some clinicians have used a combination of the two types of drugs with reasonable safety by closely supervising their patients and watching and cautiously adjusting dosages where indicated, and they have claimed good results without adverse effects. However, these drugs should not be used in combination as a routine measure until their safety, efficacy, and appropriate dosage schedules have been worked out by skilled clinical investigators. The danger is most acute when high doses of an imipramine-type or amphetamine drug are given in cases where monoamine oxidase has been inhibited to a considerable degree. In fact, death has occurred following a single injection of 25 mg. of imipramine in a newly hospitalized patient whose prior MAO inhibiting treatment was not known to the hospital staff. The need to obtain a careful history of previous drug treatment on depressed patients before initiating a new course of drug therapy is clearly evident.

However, it should be pointed out that death can also occur with ECT. The death rate is estimated to be in the ratio of 1 to 3,000 cases, as compared to the estimated death rate with iproniazid of 1 in 10,000 cases and with tranylecypromine of 1 in 100,000 cases. For purposes of comparison, death rates from the surgical treatment of peptic ulcer vary from 1 in 100 to 1 in 1,000.

Finally, the MAO inhibitors potentiate a great variety of drugs, including sympathomimetic amines (such as ephedrine), opiates (e.g., meperidine), barbiturates, methyl dopa, ganglionic blocking agents, procaine, anesthetic agents, chloral hydrate, and aspirin.

Central nervous system effects. MAO inhibitors can convert a retarded depression into an agitated or anxious one and occasionally cause hypomania or an acute schizophrenic psychosis. MAO inhibitors can also produce an acute confusional reaction, with disorientation, mental clouding, and illusions. The MAO inhibitors have been associated with altered erotic desires, edema, and muscle tremor. And they can cause dizziness, generalized weakness, slurred speech, increased muscle tone, hyperreflexia, and clonus. An occasional peripheral neuropathy, similar to that occurring from pyridoxine deficiencies and observed in connection with isoniazid treatment, can also occur.

Psychomotor Stimulants

Definition. Amphetamine, dextroamphetamine, methylphenidate, deanol, and pipradol are classified as psychomotor stimulants.

Results of treatment. Although methylphenidate may be of value in treating nonpsychiatric patients with depression, as a nonspecific psychomotor stimulant, in one study of mildly to moderately depressed patients its value was found to barely exceed that of placebo.

Moreover, amphetamine was found to be less effective than placebo in the treatment of depressed outpatients by British general practitioners; and amphetamine used in combination with chlorpromazine had a less favorable effect on chronic schizophrenics than phenothiazine treatment alone. In still another British study, amphetamine also proved less effective than phenelzine, and no better than placebo, in the treatment of depression. In a Veterans Administration study, dextroamphetamine was no more effective than placebo in treating hospitalized depressed patients.

Although relatively few studies have been done on the stimulants as a group, the data accumulated on amphetamine to date suggest that, if they differ from placebo, it is in the direction of less favorable therapeutic effect. The amphetamine-type drugs can cause jitteriness, palpitation, psychoses, and other toxic effects. Psychic dependence is common with dextro-

amphetamine, and with a combination of dextroamphetamine with barbiturates—a preparation used by “goofball” addicts. Methylphenidate can produce cardiac arrhythmias.

Interestingly, however, there is excellent evidence that amphetamines are effective in the reduction and control of hyperkinetic behavior in children, a pharmacological paradox of considerable clinical significance. These stimulants are also effective in postponing the deterioration in psychomotor performance which often accompanies fatigue, a property which may be useful in carefully selected instances.

Combined Drug Treatment

Results of treatment. Clinical experience has suggested that cases of acute psychosis with features of schizophrenia and depression will sometimes respond to imipramine-type drugs, used in combination with phenothiazine derivatives, but this has not been studied extensively in double blind studies. In a Veterans Administration study of chronic schizophrenics, the addition of isocarboxazid or imipramine to chlorpromazine did not effect greater improvement than did placebo. However, in a state hospital study, amitriptyline plus perphenazine did result in differential improvement, particularly as compared to amitriptyline alone or placebo treatment.

In brief, the value of combining imipramine-type antidepressants with phenothiazines in the treatment of the chronic retarded schizophrenic or acute depressive patients with schizophrenic features remains a matter of clinical judgment until further evidence is available. However, in the treatment of the patient with schizophrenic features, it is important to remember that, as mentioned above, the psychosis is occasionally exacerbated by imipramine when given alone (in some series of studies, 25 per cent of the patients so treated showed such exacerbation). It is also a common clinical observation that many patients treated with imipramine will often be helped by the addition of a phenothiazine derivative at the point in their recovery when they begin to get “high.”

Tranquilizers

Results of treatment. A single controlled study, done at Hillside Hospital in New York, showed a chlorpromazine-procycidine combination to be as effective as imipramine, and more effective than placebo, in the treatment of depressed patients. An unpublished study carried out at the Psychopharmacology Service Center at the National Institute of Mental Health has shown a tendency for chlorpromazine, when used alone, to be superior to placebo in the treatment of severely depressed hospitalized patients. Finally, a Veterans Administration study found that, while patients with retarded depressions do better with imipramine, patients with anxious depressions do

better with thioridazine. Clearly, then, the phenothiazines may be useful in the treatment of depression.

Rickels found that Deprol (a meprobamate-benactyzine combination) was of value in treating depressed lower class medical out-patients with many functional somatic complaints, who felt the sedative action to be consistent with the feeling of being tranquilized. These patients were alarmed by the autonomic side effects of imipramine. On the other hand, psychologically oriented depressed patients from a psychiatric clinic were helped more by imipramine, presumably because they disliked the sedative effects of Deprol.

There is also evidence that chlorthalidopoxide (Librium) has some beneficial effect on anxious Veterans Administration out-patients by increasing their vigor or energy. Chlorthalidopoxide also has a major advantage in the treatment of mild depression, as compared with phenobarbital, in that large numbers of pills may be ingested without fatal results.

Choice of Treatment in Depression

Comparative evaluations. Since two types of drugs have proven effective in the treatment of depressed patients, the question arises as to which, if either, is more effective than ECT. In Table II, the efficacy of imipramine in the treatment of depression is compared with ECT and the other antidepressant medications.

In three of the six studies comparing imipramine to ECT, ECT proved more effective; in the remaining three studies ECT was equally effective. However, other factors merit consideration as well: there is considerable disagreement as to whether ECT acts faster than imipramine, a factor of importance in the treatment of the acutely suicidal patient. But few controlled studies have been conducted to date on the kinetics of human psychopharmacology. Nor is it clear which clinical subtype will respond to which treatment. Since ECT produces a temporary memory loss, postshock confusion, and, perhaps, subtle but permanent central nervous system changes, some psychiatrists prefer not to use it as a routine measure. It has also been suggested that maintenance therapy with imipramine is necessary to prevent recurrence of depression after remission with ECT. The recurrence rate of depression following ECT is high (18 to 23 per cent after 6 months). Yet, whatever its disadvantages, it is noteworthy that of the segment of depressed patients who do not respond to imipramine, amitriptyline, or phenelzine, approximately 50 per cent will respond to ECT. Clearly, it would be important to develop methods of pretreatment identification of patients who will not be helped by imipramine (or other antidepressants) but who will respond to ECT, so that they can be started on the treatment of choice without delay.

Phenelzine has been shown to be inferior to ECT in

four studies. Isocarboxazid has also been found less effective than ECT. However, a tranyleypromine and trifluoperazine combination has been reported to result in a fairly rapid antidepressant effect, and there is some evidence that this combination can be uniquely effective in a small proportion of patients. But, again, methods have not yet been developed which would make it possible to identify these patients.

With specific reference to the antidepressant drugs, if the small number of comparative studies reported here can be considered firm evidence, amitriptyline would have to be judged superior to imipramine, while tranyleypromine, and possibly desmethylinipramine and nortriptyline, would have to be judged comparable to imipramine in efficacy. Phenelzine, and particularly isocarboxazid, would both appear to be slightly inferior to imipramine. The combined data from a number of studies on the imipramine-phenelzine comparison yielded an improvement rate of 71 per cent (138/196) for imipramine versus 62 per cent for phenelzine (101/164), which is of borderline significance (0.10 level).

And, again, the value of pretreatment determination of differential response to various types of treatment in implementing treatment should be underscored. Actually, a few observations have been made which may provide clues to potential response. It has been suggested that a patient with a genetic relative who responded well to either an imipramine-type drug or a MAO inhibitor will respond more often to that type of drug than to another. It has also been suggested in two studies that imipramine responders remove imipramine from the blood stream at a different rate than do nonresponders. Similarly, it might be possible to predict response to MAO inhibitors on the basis of a biochemical test of actual MAO inhibition. It has also been suggested that a pretreatment high salivation rate or low arteriovenous glucose difference might predict the patient's future response to MAO inhibitors. Finally, it has also been suggested that cases of hysteria, with secondary depression, respond best to MAO inhibitors.

The fact that one type of antidepressant is completely ineffective in a given patient, while another drug produces a dramatic effect, is another indication that the antidepressant acts to correct a pre-existing deficit and is not a general euphoriant. It should be pointed out, however, that studies which identify a specific type of patient as responding differentially to a drug should be regarded as only tentative until they have been cross-validated. When one considers such data in relation to a large number of clinical dimensions, it becomes obvious that in some instances good responders are separated from bad responders only by chance. It will be of considerable interest to see whether future research will successfully identify a specific type of patient who re-

sponds differentially to any one of the major existing forms of treatment for depression—ECT, imipramine-type drugs, or MAO inhibitors.

In summary, imipramine-type drugs are probably slightly more effective and slightly safer than MAO inhibitors. Conclusive evidence is not yet available which would indicate that any of the three newer imipramine-like drugs is preferable to either imipramine or amitriptyline. However, there does appear to be some basis for preferring amitriptyline in the treatment of severe depression. Phenothiazine derivatives and antianxiety agents may also be of value in selected cases. In the absence of clear cut differences, it is, of course, better for the clinician to be highly familiar with the assets and liabilities of a small number of drugs than to be minimally informed and experienced in the use of a large number of drugs. At the same time, the literature on the newer antidepressants should be examined periodically to see whether newer agents have been demonstrated to have any advantages over the older drugs or whether more clear cut differential indications for the use of older drugs in specific types of depressed patients have been developed.

Indications and contraindications. As pointed out earlier, most of the side effects experienced by patients receiving antidepressant drugs are not actually drug-related. In general, the antidepressants are quite safe, and, while potentially dangerous side effects do occur, they are rare. Since they do occur, however, and these drugs are quite potent, they should only be prescribed when there are definite indications that such treatment is necessary.

Under normal circumstances, there is not medical need for weekly routine laboratory tests when either type of antidepressant is used, although appropriate investigations should be made when there is evidence of physical disease before administration of the drug. Occasionally, in a single liver function test, small transient abnormal values occur, particularly in chronic psychotic patients. These are not a contraindication to initiating drug therapy; nor are they an absolute indication that the drug should be discontinued; rather they indicate the need for further investigation and repetition of the test, to check for laboratory error.

Since patients can successfully commit suicide with antidepressant medication, their use should be closely supervised in the potentially suicidal patient.

Finally, although this section has not concerned itself with the psychotherapeutic treatment of depression, effective psychotherapy may greatly enhance the patient's response to antidepressant drugs. Moreover, depressions in patients with underlying neuroses or personality disorders may respond dramatically to psychotherapy and not respond at all to existing drugs.

The stakes are fairly high in the more serious depres-

sions. The average untreated depression often runs for 6 months or more before spontaneous remission occurs, if it does. It has been estimated that about 15 per cent of this population eventually commit suicide, and about 20 per cent have multiple recurrences. It is recommended, therefore, that the physician be familiar with an effective antidepressant drug for each type of illness (and for each type of patient) and that he administer it, when indicated, in the dosage considered to be most effective.

35.3 SEDATIVES

ROBERT L. SHAROFF, M.D.

History

Today, the majority of psychiatrists consider the use of sedative drugs (i.e., barbiturates, bromides, etc.) a valuable tool in the armamentarium of the psychotherapist, when such measures are dictated by valid therapeutic goals and follow a carefully planned course. This viewpoint has evolved over a period of time.

Barbiturates were introduced into medicine by E. Fischer and J. von Mering in 1903. According to Malamud, the first extensive use of drugs to induce sedation occurred shortly afterward, when the protest against the use of mechanical restraints became so vehement that hospitals were forced to curb their use. Chemical restraints were then substituted for mechanical restraints. As time went on, however, the injurious effects of chemical restraints were noted; concomitantly, psychiatrists began to realize that sedatives had a place in psychiatry and that their function need not be restricted to providing another form of restraint.

Freud wrote, in 1922 and again in 1933, of the need to use chemical agents to cope with the powerful psychological forces at work in certain psychiatric conditions, without specifying the properties of such agents. In fact, sedatives had been used for therapeutic purposes, for the first time, in the period following the First World War. And in 1922, Klaesi reported good results in the treatment of schizophrenia by continued narcosis, using Somnifen. However, the use of Somnifen for such purposes never gained full acceptance, for a variety of reasons. For one, its therapeutic value was questioned; secondly, there were reports of complications, such as the development of intercurrent infections.

In 1930, Bleckwenn reported on his experiences with the use of barbiturates in the treatment of mental disorders. Over a 10-year period, he found that the emotional state of the patients so treated had been altered by the drug to the extent that their contact with reality improved. These findings led, in turn, to the idea that such drugs might be helpful in psychotherapeutic situations where emotional contact with the patient could not be established otherwise, due to the nature of the illness.

Current Application of Sedative Drugs in Psychiatric Treatment

Rationale. The rationale for the use of sedatives in psychotherapy, as stated below, follows Kubie's formulation. The sedative acts as a psychic analgesic and in so doing allows the patient to withstand such un-

pleasant emotions as rage, anxiety, and guilt. As a result, painful areas of experience may be explored without immediate withdrawal or repression. In this way, the drug aids in the recovery of repressed and dissociated experiences which played a role in the etiology of the patient's illness. And, at the same time, interpretations which would cause psychic pain under other circumstances may be accepted, integrated, and synthesized in a healthier and more mature manner.

In general, the barbiturates are the most commonly used sedatives. Depending on the effect to be achieved, one may prescribe one of the rapid, short-acting derivatives, such as pentobarbital (Nembutal), or, on the other hand, an intermediate-acting barbiturate, such as amobarbital (Amytal), may be deemed more suitable. In still other instances, when the goal is a long-acting effect, phenobarbital may be the sedative of choice. In addition, bromides, chloral hydrate, paraldehyde, scopolamine, and, occasionally, the antihistamines may be used for sedative purposes. Nor does this represent an exhaustive list of the drugs that may be used for purposes of sedation. However, it is sufficiently inclusive to cover most situations in which the use of sedatives is deemed advisable, in conjunction with the psychotherapeutic process.

Action. In general, the basic function of the sedative drugs is to promote relaxation by decreasing restlessness and irritability. More specifically, by their depressant action on the limbic system and the hypothalamus, all the sedative drugs, and the barbiturates in particular, neutralize overly intense affective discharge from the autonomic and vegetative centers. Thus, their depressant action on the reticular formation and neocortex may induce feelings of ease, and even mild euphoria at times.

The use of the tranquilizing drugs in psychiatric treatment is described in detail elsewhere in this volume (Section 35.1). However, the specific differences between the tranquilizers and the barbiturates merit brief discussion in this context. Unlike the ataractics, the barbiturates usually do not have normalizing effects (antipsychotic action) on psychotic patients. The barbiturates also differ from the ataractics in their more marked depressant action on the cortex. These drugs are similar in their calming effects. However, in contrast to the tranquilizers, a dosage of barbiturates sufficient to induce sedation frequently causes diminished consciousness and sleepiness as well. Obviously, then, when barbiturates are used in the management of psychiatric patients, this should be borne in mind and the dosage adjusted accordingly. Otherwise, instead of inducing relaxation, the drug may cause the patient to fall asleep, thereby precipitately terminating the psychotherapeutic process. Finally, as noted above, the sedative drugs are central nervous system depressants, and, consequently, they all impair cognitive functions to some degree, depending on the dosage administered. The tranquilizing drugs, on the other hand, have the ability to modify affective

states without seriously impairing cognitive function. As a result, they have replaced the use of sedatives to a great extent, especially in the treatment of the psychoses, although on occasion both may be used in conjunction.

Indications. Sedatives serve various functions in psychiatric therapy. They may be prescribed for relatively short periods of time, during specific critical situations in the psychotherapeutic process. At other times, they may be used as emergency measures to control severely disturbed and agitated behavior. Again, mild sedation may be administered when it is anticipated that the patient may be exposed to excessive emotional stress. Finally, and most important, sedatives are helpful in the management of insomnia and other sleep disturbances which often complicate existing psychiatric conditions.

Contraindications. More prolonged use of sedatives may be indicated when the patient appears to be in a chronic state of acute anxiety or agitation, which interferes with the psychotherapeutic process. However, in situations where the prolonged use of sedation is indicated, the physician must be alert to the possible side effects of the drug. These may include insidious toxic effects which may be manifested by the appearance of an organic brain syndrome. The physician should also be alert to allergic and other idiosyncratic reactions to the use of sedative drugs, which may take the form of fever, rash, manic excitement, or even delirium. Unusual reactions to barbiturates have been reported in patients with diabetes mellitus and hyperthyroidism. Congestive heart failure should be considered a possible contraindication; other physiological contraindications to the use of sedatives are liver and cardiorenovascular disorders. Finally, extreme caution should be used in prescribing barbiturates for patients with fever, and for older or debilitated patients.

There are other contraindications as well. According to recent reports, an increasing number of patients have become addicted to the sedative drugs, especially to the barbiturates. And the barbiturates have also been used to an increasing extent in suicide attempts. These hazards clearly indicate that the use of sedatives by patients who appear to be suicidal or prone to addiction must be carefully supervised. In a broader sense, however, they also indicate the need for periodic review of any prolonged sedative regimen.

35.4 NARCOTHERAPY

ROBERT L. SHAROFF, M.D.

Introduction

Definition. The term "narcotherapy" refers to the intravenous injection of drugs into the patient, as an adjunct to psychotherapy. More precisely, this procedure derives from the premise that the creation of an altered state of awareness or consciousness will facilitate the diagnosis and treatment of psychiatric illness. At one time or another, alcohol, ether, nitrous oxide, all the modern barbiturates, and the hallucinogenic drugs, have been used to this end. At present, however, the two drugs employed most commonly for this purpose are sodium Pentothal and sodium Amytal; this discussion will deal primarily with the use of sodium Pentothal.

History. Bleckwenn was the first to advocate the intravenous injection of sodium Amytal in psychiatric conditions. Subsequently, in 1926, Horsley originated the term "narcoanalysis," which involved the use of both sodium Pentothal and sodium Amytal. However, the application of these drugs was studied most extensively by Grinker, in relation to short term, emergency psychotherapy of the war neuroses. He described this procedure as "narcosynthesis."

Techniques. The use of intravenous injections of barbiturates may vary in terms of procedures involved, which, in turn, will depend on the specific treatment goals. Attempts have been made to classify existing techniques on the basis of the structure and goals of the interview. Thus they have been variously described as (1) narcosynthesis, (2) abreaction, (3) narcoanalysis, (4) narcosuggestion and hypnoanalysis, and (5) narcoplexis. In fact, these terms are often confusing, and a simpler classification seems appropriate.

Essentially, three techniques are utilized in narcotherapy which may be described as follows.

Simple catharsis. The use of the Pentothal interview simply to facilitate catharsis is the technique used least frequently. In addition, it is probably the least effective application of narcotherapy. In brief, the disturbing conflict is elicited with affect (abreaction). However, the material uncovered is not ade-

quately integrated into the total personality. Consequently, while the experience may be effective, its long term results are relatively unpredictable.

Suggestion. The therapist makes suggestions to the patient while he is under the influence of the drug, without attempting to uncover repressed material. Thus, this technique resembles supportive psychotherapy, and, as is true of all treatment procedures based on suggestion, while it may have some temporary value, the ability of the patient to maintain his therapeutic gains is questionable.

Narcoanalysis and narcosynthesis. Both of these procedures involve the subsequent application of psychotherapeutic techniques to help the patient integrate and work through the material that has been elicited through the use of the drug.

Pentothal Interview

Rationale. The Pentothal interview helps the patient to establish a relationship with the therapist, which may be the first step in altering his view of the world and his environment, so that he no longer sees these as completely hostile forces in relation to his needs and desires. More specifically, the patient's illness and symptoms have served as a protection against the breakthrough of the anxiety which surrounds his underlying conflict(s). The drug appears to lessen this anxiety so that the patient can better tolerate expression of painful psychic material. This expression, in turn, facilitates the process of exploration. In some patients, the drug seems to produce a mild euphoria and to weaken inhibiting mechanisms as well. In any event, the over-all effect of the Pentothal injection is to enable the patient to tolerate painful insights and to incorporate them into his emotional and intellectual life.

Dosage. Sodium Pentothal is marketed for intravenous use in the form of sterile powder in ampules of varying strength. Pentothal solutions are used in concentrations ranging from 2.5 to 5 per cent. Usually, the dosage required for satisfactory narcosis varies between 0.25 and 0.5 gm., although more than 1.0 gm. may be necessary for larger individuals in extreme states of agitation. As might be expected, the effect of the drug will vary, at least to some extent, with the strength of the concentration of the Pentothal solution, the dosage administered, and the rate of injection. In addition, other variables, such as the patient's age and weight, previous food intake, previous barbiturate ingestion, and his cross-tolerance to other sedatives (for example, glutethimide) will also influence the effect of the drug.

Administration. Before administering the drug, the physician should establish a positive rapport with the patient. More specifically, the patient is told that the drug will help him to relax and feel more at ease, and that it will permit him to talk more freely and comfortably about the feelings and experiences that bother him. Concomitantly, common misconceptions

that Pentothal is a magic truth serum should be dispelled.

The drug is best administered in a quiet room, with the patient in a reclining position. The injection is made into an antecubital vein. When the 5 per cent Pentothal solution is used, the injection is made at the rate of 2 cc. per minute. When the weaker solution is used, the injection is made at a more rapid rate. During the injection, the patient may complain of a peculiar taste in his mouth; in addition, in many instances, there is some initial increase in anxiety or agitation. However, as the injection continues, these symptoms tend to disappear.

At the outset, and until the physician becomes familiar with the patient's characteristic response to the drug, it is best to ask him to count backward from 100 immediately after the injection is made. Shortly after counting becomes confused, but before the patient actually falls asleep, the injection is stopped. It is at this point that psychological interaction between patient and therapist occurs. It is at this point that attempts are made to discuss significant material, to elicit repressed experiential data, or to make appropriate suggestions. The patient is then permitted to go to sleep.

Indications. The effect of Pentothal injections may, of course, be quite dramatic in cases of hysterical amnesia. However, the Pentothal interview may serve an equally important function in relation to problems more commonly encountered in clinical practice. Thus, the procedure may provide symptomatic relief for severely agitated patients. Where psychotherapeutic exploration seems blocked, it may constitute a new therapeutic approach. At other times, it may facilitate ventilation of significant life experiences which played a vital etiological role in the patient's illness.

The Pentothal interview may be used as a diagnostic and prognostic tool as well. The injection may elicit suicidal or paranoid ideas which might not be detected otherwise. It can be used in differential diagnosis to help distinguish organic disabilities from functional syndromes. And it may also be used as a test for organic brain disease, inasmuch as it provokes neurological symptoms which may not be apparent under "normal" conditions. In addition, in the course of the interview, such mental symptoms as confabulation, disorientation, and denial of illness, which may not have been apparent previously, frequently emerge in response to direct questioning.

On occasion, the drug has aided in the differential diagnosis between the catatonic stupor of schizophrenia and stuporous depressive state. Ordinarily, it is difficult to differentiate between these psychopathological entities on the basis of clinical data. The Pentothal interview has led to the formulation of spe-

cific criteria to facilitate such differentiation. In the depressed patient, an intravenous injection of barbiturate will usually result in a deepening of the stupor and/or sleep. In schizophrenic patients with catatonic stupor, such an injection often produces a temporary clearing of the stupor, during which the patient may communicate rationally with the therapist, at least briefly.

Finally, the Pentothal interview has also been used in legal investigations. However, the present consensus is that there is no certainty that the subject will "confess" under the influence of the drug, or, if he does, that his account will be accurate. Moreover, the courts have adopted a rather paradoxical attitude toward this procedure: information obtained in the course of Pentothal injections is not admitted as legal evidence, yet the psychiatric implications of such data may carry considerable weight.

Contraindications. Intravenous Pentothal injections are contraindicated in the presence of any medical illness which would contraindicate the use of barbiturates, e.g., severe cardiac impairment, porphyria, kidney dysfunction, or liver pathology. General disability, marked emaciation, or severe anemias are other reliable contraindications. Finally, for the most part, the procedure should be limited to adults.

General considerations. As is true of any other procedure which may alter the individual's state of awareness, it is advisable to obtain the patient's written consent to this form of intervention in advance. In addition, when milder doses are administered to an ambulatory patient, the patient should be permitted to rest after the interview and should not leave the physician's office unaccompanied.

As mentioned earlier, the nature of the Pentothal interview will depend on the psychiatrist's therapeutic goal, which may range from symptomatic relief to the uncovering of deeply repressed material, in order to effect the basic reintegration of personality. It should be borne in mind, however, that the Pentothal interview is not an isolated treatment experience. No matter how limited (or extensive) his treatment goals, the psychiatrist who conducts the interview must have a fundamental knowledge of the psychodynamics of his patient's emotional and mental functioning.

35.5 THE CONVULSIVE THERAPIES

LOTHAR KALINOWSKY, M.D.

Early Experimentation

Convulsive therapies, which continue to be a widely used modality of treatment, were introduced by von Meduna on the basis of two different observations. It had been noted for a long time by mental hospital physicians that patients would suddenly lose their symptoms when they had a spontaneous convulsion, no matter what caused it. The second line of reasoning was based on various statistics showing that epilepsy and schizophrenia hardly ever occurred in the same patient.

Metrazol treatment. In 1935 von Meduna reported systematic attempts to induce convulsions in schizophrenics. He first used camphor in oil, which he injected intramuscularly. This proved to be unreliable because it was difficult to anticipate the time the patient would have the convulsion. Some would have several convulsions, and others none at all. Von Meduna, therefore, changed to a soluble synthetic camphor preparation, pentylenetetrazol (Metrazol). This could be injected intravenously as a 10 per cent solution. In the majority of cases it produced a convulsion within 30 seconds with a dose of 5 to 10 cc, injected rapidly.

Most of the experience with convulsive therapy—its indications, contraindications, and complications—was with Metrazol treatment. This method is still preferred by some workers, but as a whole it has been replaced by the technical modification of electric convulsive therapy (ECT). Most of the facts described in this section regarding ECT are equally valid for Metrazol treatment.

Indoklon. Before ECT was introduced, other authors had experimented with different convulsive agents of a pharmacological nature. Most of them turned out to be less reliable, and some more dangerous than Metrazol. None of them is still in use at the present time with the exception of the newest of them, hexafluorodiethyl ether, known under the trade name of Indoklon.

Indoklon was found by the pharmacologist Krantz and his co-workers while studying aliphatic fluorinated ethers for the purpose of anesthesia. One of these, hexafluorodiethyl ether, was found to be a convulsant and was, therefore, called Indoklon. It was originally and mostly still is applied as an inhalant by means of a mask and a vaporizer loaded with gauze saturated with the liquid. Since it also has an anesthetic phase, the patient first loses consciousness, then has some myoclonic movements, and finally develops a tonic-clonic convulsion similar to that in any other form of convulsive therapy. Indoklon can also

be applied intravenously; then it hardly differs from Metrazol or other pharmacological agents. However, at the time of this writing, the intravenous Indoklon has not yet been approved for general use by the Food and Drug Administration, and Indoklon convulsive therapy is primarily used by inhalation.

Techniques of Electric Convulsive Treatment

Electric convulsive treatment, also called "electroshock treatment" by a misnomer, was introduced by the Italian psychiatrists Cerletti and Bini in 1933. Its application being much simpler and more reliable, it soon replaced Metrazol treatment.

A simple apparatus using alternating current was built by Bini. Most machines are still based on his original model. Other machines have been introduced over the years, and a great controversy developed over whether there are better types of current than the alternating one. Some workers use unidirectional current and claim that this produces less confusion. The same claim was made for brief stimuli techniques, in which brief stimuli replace the 60 per second stimulation of the ordinary alternating current. Other machines combine unidirectional and brief stimuli techniques. No convincing evidence has ever been given to prove that the memory impairment is actually reduced with these modified currents. The newest attempt in this respect is made by workers using unilateral stimulation of the nondominant hemisphere.

Electrodes and current. In the standard technique, electrodes are applied to both temples. Here, too, many different types of electrodes have been used for the application of the current, without any one of them proving convincingly superior to the others. Skin resistance must be decreased by a salt water solution or with the safer method of electrojelly, similar to the one used in electrocardiography.

The amount of current applied by the originators of the method was 70 to 130 volts for 0.1 to 0.5 second. Attempts have been made to measure the actual amount of current that passes through the brain, but the amounts found varied between 200 and 1600 milliamperes.

Muscle relaxants. The present day technique used by the majority of workers is modified by muscle-relaxant drugs such as curare. Such muscle relaxation is needed to prevent fractures during the convulsion. A. E. Bennett first introduced curare to paralyze the muscles. A concentrated aqueous extract of curare was later replaced by various synthesized curare-like preparations. Although an antidote for curare exists in the form of Prostigmin, which was routinely given immediately after the convulsion, fatalities occurred, probably due to some central effect of the curare. Curare was, therefore, replaced by succinylcholine, discovered by Bovet of Italy and introduced in psychiatry by Holmberg of Sweden and Arnold and Boeck-Gréissau of Austria.

Preparation. The technique used in conjunction with the anesthesiologist is as follows. The patient can feel the effect of the muscle relaxant, since succinylcholine suppresses his respiration, so he is first anesthetized with a short-acting intravenous barbiturate injection. The drip method is preferred for the introduction of the barbiturate as well as for the succinylcholine. Syringes for the barbiturate and the succinylcholine are also used. It is not advisable to mix the two preparations because the patient is apt to feel the succinylcholine acting on his respiration before he falls asleep. Psychiatrists should be able to do this themselves, although it is certainly safer to have an anesthesiologist give this premedication because he will be better prepared to handle complications if they occur.

There is no doubt that complications can occur in ECT modified by anesthesia and muscle-relaxant drugs. This is particularly true for patients with myocardial disease and for hypertensives, for whom any anesthesia with barbiturates represents a certain risk. Therefore, premedication with barbiturates in patients with cardiac complications should be avoided. This can be done by starting the treatment with succinylcholine and, before the patient feels respiratory distress, applying a small amount of current, a so-called subconvulsive stimulus, to make the patient unconscious. As soon as the patient's musculature is relaxed, the actual convulsive stimulus follows.

Manifestations. The manifestations of electrically induced convulsions resemble those of a spontaneous convulsion with certain differences. If the amount of current given is not sufficient, the patient will only lose consciousness (*petit mal* response). If somewhat more current is given, the patient may have a delayed convulsion; that is, he will lose consciousness and, after only a few seconds, will go slowly into the tonic phase followed by the clonic phase. If still more current is used, he will have an immediate convulsion in which the tonic phase starts at the moment of the stimulation.

The tonic phase lasts about 10 seconds, and the clonic phase 30 to 40 seconds. It is important that this time relationship be watched carefully. In modified convulsions with muscle-relaxant drugs, it is sometimes difficult to see any movements. However, a slight plantar flexion of the feet can be noticed as evidence of the tonic phase; after approximately 10 seconds, some toe or other movements should indicate the clonic phase. If none of these manifestations is noted, it is wise to give a second stimulus.

In pharmacological convulsive therapy, particularly with Indoklon, myoclonic movements of various kinds precede the tonic phase and are sometimes mistaken by the inexperienced for the actual convulsion. It may be added that the succinylcholine, prior to its paralyzing action, may lead to rather vivid muscular

fasciculations, which, however, cannot be easily mistaken for a convulsion.

The convulsive threshold or the amount of current necessary for a convulsion changes among individuals. Male patients usually have a lower threshold than females, and younger people a lower one than older persons. Barbiturates may, of course, raise the threshold considerably. No patient fails to convulse if an adequate amount of current or repeated electric stimuli are given.

After the convulsive movements have stopped, the patient remains in a state of apnea, which may be prolonged if muscle-relaxant drugs are used. In this case it will be necessary to apply oxygen with a rubber bag until the patient resumes respiration.

Preparing the patient. The preparation of the patient is simple. He is not to have food in his stomach; therefore, he should be treated in the morning without breakfast or in the afternoon after having a light breakfast and no food for at least 4 hours before treatment. The bladder must be voided. Dentures are usually removed, although in patients with partial dentures it is safer to leave them in because irregularly spaced teeth may break during the contraction of the jaw. Mouth gags of various types are used to protect the teeth and the tongue. Even in ECT with muscle-relaxant drugs, although most muscles are paralyzed, the jaw muscles may still contract quite strongly.

Patients regain consciousness after a few minutes but remain in a clouded state for 15 to 30 minutes. It is advisable to keep them in the treatment area for at least 1 hour.

Treatments can be given in ambulatory facilities in hospitals and in private offices, but the patient should be accompanied by someone, kept for at least 1 hour for observation, and be taken home by somebody.

Changes during ECT

Many medical observations have been made on patients under ECT, but even such simple tests as blood pressure changes and changes in heart rate show rather contradictory results. The present technique of ECT modified by anesthesia makes such observations even more difficult to evaluate. The same is true for changes in the respiratory rate. Hematological and serological changes are also quite contradictory in the reports available. Since these studies contributed nothing to the understanding of the treatment, the reader interested in these findings must be referred to special monographs on the subject.

Endocrinological changes. Endocrinological changes occurring during an ECT series are rather constant. The most frequent observation is an increase in weight, which may be due to an effect on diencephalic centers. It has also been noticed that menstrual

changes in the form of amenorrhea for 1 or 2 months occur frequently.

Neurovegetative changes. These changes are the basis for the prognostic Funkenstein test. This test tries to establish the prognosis of ECT on the basis of the response to epinephrine chloride and Mecholyl bromide. Patients have a good prognosis for ECT if they have more than a 50 mm. Hg rise in systolic blood pressure after intravenous injection of 0.5 mg of epinephrine and a fall of blood pressure after 10 mm. of Mecholyl intramuscularly with failure to return to their normal blood pressure within 25 minutes. The same is true for those who respond to Mecholyl with chills. There is some controversy about the validity of the test, but, even if the response is clear cut, the therapist should probably not exclude a patient from treatment because the test suggested a poor prognosis.

Psychopathological changes. Psychopathological changes consist primarily of amnesia for the whole treatment procedure and, after several treatments, memory impairment, which may last for one or several weeks after termination of treatment. Investigations by many groups of psychologists have shown convincingly that no lasting loss or impairment of memory occurs.

Some patients, on waking up from the treatment, misinterpret their surroundings and react with an excitement state. They should receive a barbiturate drip for 20 minutes after the convulsion. In rare cases the psychopathological changes during ECT may be complicated by various types of organic reactions, with hallucinations different from those for which the patient was treated.

Apart from the intellectual changes of memory impairment, the patients always show emotional, organic changes, such as euphoria or complete affective dullness. The intensity of the organic reaction depends on the number and the spacing of the treatments. This is best exemplified by a procedure that has been recommended and is being used by several workers in the field in order to bring the patient to the deepest possible state of organic dementia. To achieve this, they give treatments every day and even three or four treatments within 24 hours. The patient is brought to a point where he becomes incontinent of urine and feces. Such regression is considered by some a wanted accompaniment of convulsive treatment; but in the author's experience, the organic psychiatric changes do not determine the outcome of the treatment. However, these deep confusional states clear up entirely within a week or 10 days, and they do not leave any lasting memory impairment or personality changes.

The patient may have an amnesia for the entire series of treatments, not only when a deep degree of organicity has been reached. Patients in whom the sensorium remains perfectly clear may show later that they cannot remember some occurrence during the

treatment, even though they may have responded to it in an apparently normal way.

Fear of treatments. A most vexing psychopathological phenomenon is the fear the patient has of the treatment. He has one type of fear before the first treatment that is probably due to the name "shock" treatment and anything he may have heard about it. He is relieved of this fear after the first treatment, when he realizes that he did not have any discomfort during the treatment.

However, after several treatments another type of fear sets in, which does not leave the patient until he has finished the series. He remains aware of the fear, though unable to give a reason for it, and it recurs when he has to undergo treatment again at a later date. This fear seems to be a result of the unpleasant experience of waking up after the treatment and not knowing who he is and where he is. This loss of one's own identity is usually not given by the patient as the reason for his fear, but the fact that it is first realized a week or so after the first treatment, when the amnesia for the incidents surrounding the treatment have subsided, suggests that this does explain the treatment fear of almost all patients.

Neurological changes. Neurological observations are essentially identical to those made in any generalized convulsion. No reflexes can be elicited during and shortly after the convulsion. After a period of flaccidity, pyramidal signs may appear. The pupils do not react for a while, and then they may oscillate between rigidity and reflex activity. Constriction of the retinal vessels has been observed in delayed reactions prior to the onset of the actual convulsion, as is seen in epileptics, and is followed by vasodilation of the retinal vessels. Postconvulsive motor phenomena may consist of various involuntary movements and automatisms, which should not be mistaken for a second convulsion. Aphasia, agnosia, and other disturbances of cortical function can also be observed.

Electroencephalographic findings also repeat essentially those seen in spontaneous convulsions. After each convulsion there is a slow wave pattern that returns to normal after 5 to 30 minutes. After several treatments the abnormal pattern remains, and various electroencephalographic changes indicate the cerebral dysfunction during a series of electrically or pharmacologically induced convulsions. After the treatments have been discontinued, the electroencephalogram may remain abnormal for several days or weeks. After 2 or 3 months at the latest, the electroencephalogram returns to normal in all cases.

Complications and Contraindications

In convulsive therapy, these have been much discussed. It was surprising to many observers that, with the exception of fractures in unmodified ECT, complications are extremely rare. It was soon recognized that many expected complications did not occur. This

was the case in such conditions as severe hypertension, heart disease, and tuberculosis. In patients afflicted by such physical diseases, the seriousness of the mental disorder often made it necessary to take certain risks and to treat such patients because the agitated state of the patient was a danger in itself and had to be removed by means of convulsive therapy. It was then realized that the electrically induced convulsion is not different from a spontaneous one, and the extensive literature on epilepsy has amply demonstrated that no preexisting disease becomes worse when an epileptic patient has convulsions, even frequent ones. This, in accordance with the growing experience with ECT, explains why most physical ailments do not represent a contraindication to this treatment.

The same is true for such physiological conditions as pregnancy. ECT is not dangerous during the first months to mother or child, nor does it accelerate the termination of pregnancy. Many follow-ups have proved this point. It may be also mentioned that age is no contraindication to ECT: both young children and very old persons can be treated.

Fractures. The most frequent complications in convulsive therapy prior to the introduction of muscle-relaxant drugs were fractures. There were two main types of fractures. The most frequent ones were those occurring in the dorsal spine between the fourth and eighth dorsal vertebrae. They consisted of varying degrees of compression fractions in these vertebrae. They have little clinical importance. In many instances they were not accompanied by pain; in others the pain could persist for several weeks or, rarely, months. In no instance were they an indication to discontinue ECT or to institute orthopedic measures. No neurological complications were ever observed in connection with these fractures, which, as in tetanus, occur in the rigid part of the spine, although they may occur in several vertebrae in the midthoracic area.

Another type of fracture is that of the long bones, which occurred most frequently in the head of the humerus and the head of the femur. They were rare, although clinically much more serious than those of the spine. As with all fractures in convulsive therapy, they are explained by the muscular contraction. This is well demonstrated by the fractures in the region of the hip, where the sudden contraction of the adductor muscles may lead to a fracture of the head of the femur or, if this resists the impact of the muscular contraction, the entire head of the femur may be pushed into the pelvis, thus causing an extremely rare acetabular fracture.

There is no evidence that any of these fractures are caused by osteoporosis; rather, they seem to be due to some unusual configuration of the bone-muscle relationship. This may explain, for instance, why acetabular fractures (in the exceptional cases that have been described) usually occurred bilaterally and during the first treatment.

These complications are no longer a problem when muscle-relaxant drugs are given. On the other hand, there are still many hospitals where the risks of the anesthesia technique are considered too high and unmodified ECT is still given. Therefore, acquaintance with this type of complication is necessary. There has been much discussion about these fractures not occurring in spontaneous epileptic seizures. This is probably because epileptics go slowly into a convulsion, but therapeutic convulsions usually start suddenly.

Fatalities. Fatalities were extremely rare even before the introduction of anesthesia techniques in convulsive therapy. Some statistics found a death rate of up to 0.1 per cent for ECT, but they probably included cases where death occurred during a course of ECT but was obviously unrelated to the treatment. This relative safety of artificially induced convulsion is again in accordance with the experience that epileptics do not die during convulsions. In rare cases, cardiac arrest or death due to apnea has been described in unmodified ECT. There have also been individual reports on patients who had a postconvulsive excitement state, causing cardiovascular collapse.

There is the definite impression that the anesthesia technique increased the number of fatalities, although no figures are available. It is obvious that in patients with myocardial disease the repeated barbiturate anesthesia during a series of ECT is a danger in itself. In hypertensives both the barbiturate anesthesia and the convulsion may produce a sudden fall in blood pressure. In some patients coronary occlusion has been described, usually $\frac{1}{2}$ or 1 hour after the convulsion.

Contraindications. It can be stated that there are almost no absolute contraindications to ECT, as proved by the large numbers of patients with myocardial disease or recent coronaries treated successfully with ECT. However, psychiatrists must be aware of the potential danger in myocardial disease and recent coronary thrombosis and must carefully weigh the risk of the treatment against the risk of continued agitated states in a patient afflicted with those diseases. The avoidance of barbiturate anesthesia, by administering succinylcholine and replacing the barbiturate with a subconvulsive stimulus as described before, is a good way to eliminate the danger in such cases.

Brain tumors. This remains the one contraindication. Although all other neurological conditions can be treated without any damage, it appears that the sudden increase of intracerebral pressure during a convulsion represents a great danger to patients with brain tumors. Several fatalities as well as the appearance of severe neurological symptoms have been described in cases where the brain tumor had simulated a depression and ECT had been applied for this reason.

Other possible contraindications. As far as other contraindications are concerned, peptic ulcer, sub-

dural hematoma, and other conditions that might have led to hemorrhage in unmodified ECT rarely did so. Even large aortic aneurysms did not rupture in unmodified ECT. These conditions thus do not represent a contraindication when muscle relaxation is used.

A frequently asked question is whether eye diseases such as glaucoma and threatening detachment of the retina are contraindications. Actually, it has been shown that the intraocular pressure during a convulsion decreases rather than increases. Therefore, no complications in such conditions have occurred. There is, however, the danger that the muscle relaxant succinylcholine will increase intraocular pressure, and in patients with glaucoma, eserine should be given prior to the treatment.

Neuropathological changes were discussed in the literature shortly after the introduction of convulsive therapy. Some animal experiments seemed to show certain pathology, but this was not confirmed by numerous extensive studies by most workers. In those few instances where fatalities occurred in humans, no pathology of any kind was found.

In summary, it can be stated that aside from brain tumors there are *no absolute contraindications* against convulsive therapy. However, the seriousness of the physical illness and of the psychiatric disorder must always be carefully weighed against each other.

Indications and Results

Convulsive therapy was introduced as a treatment for schizophrenia. Only 4 years after its introduction, it became noticeable that the best results were obtained in depressions. Today it can be said that, contrary to the theory of antagonism between convulsion and schizophrenia, on which convulsive therapy was based, this type of therapy is useful in many different conditions. Since the introduction of drug therapy, the indications for ECT have become more restricted, and for a while it seemed that this treatment could be limited to fewer patients than before. Lately, however, the increase in the application of convulsive therapy has been considerable. Its indications have not been changed, but in many instances pharmacotherapy will be tried first and ECT left to refractory cases. In other instances the acuteness of the psychopathology requires immediate ECT.

Depression. The effect of ECT in depressions is one of the most spectacular treatments in medicine. Both retarded and agitated depressions of a psychotic nature clear up after three or four convulsive treatments. It is then advisable to give two or three more treatments in increasing intervals to stabilize the result.

Most depressions respond to ECT. This is as true for patients who change from manic to depressive states as it is for those who have only recurrent de-

pressions. Involutional melancholia of a pure nature, not complicated by schizophrenic features, also responds to a short course of six to eight ECT. This is also true in depressions of old age, as long as they are not caused by arteriosclerosis or senile brain changes. It is one of the most gratifying therapeutic experiences to examine psychiatrically so-called senile patients with agitation, to find that they actually do not suffer from senility but from affective psychoses, and then to remove their psychiatric symptoms with a few ECT.

In so-called reactive or neurotic depressions, the results are less reliable. It appears, though, that many of these cases respond extremely well, especially those patients who have true depressive episodes but are at the same time neurotic. The so-called atypical depressions, which last longer and are mixed with neurotic and often schizoid features, respond less well. These patients usually have a more superficial depressive affect and a great variety of psychosomatic complaints. In such cases the antidepressant drug, iproniazid (Marsilid), which was withdrawn in this country because of liver complications, has been reported to be effective by some English investigators. The presently available drugs have less convincing results in these atypical depressions, and one has to resort to ECT in order to achieve at least a temporary symptomatic effect.

Danger of suicide. The much discussed question of whether depressions should be treated first with antidepressant drugs or with ECT is difficult to answer. There is one all-important factor in favor of ECT: the danger of suicide. There is general agreement that in nonhospitalized patients the suicidal danger is a definite indication for immediate ECT. We have no convincing signs to indicate which patient is suicidal and which is not. Since the introduction of the antidepressant drugs, serious mistakes have been made in judging apparently mild depressions as non-suicidal and then losing the patient in a suicide. It has long been known that the patient most likely to commit suicide is not the severely retarded depressed patient, who has often lost the initiative for suicide, but rather the patient who goes into or comes out of a depression. It appears that, in patients treated with antidepressant drugs, the paralyzing depressive effect diminishes, but the depressive thought content continues, and the patient regains sufficient initiative for the suicidal act. An increasing number of such cases seem to be the main reason for the greater preference given to ECT at present.

The time factor. Time is another important consideration in favor of ECT. Patients unable to continue in their work frequently risk the loss of their jobs if the slow-acting drugs are not effective and have to be followed with ECT. In hospitalized patients, the expense of several weeks' stay for an often unsuccessful antidepressant medication also suggests an immediate course of ECT. Therefore, both medical and social

considerations explain why ECT continues to be the treatment of choice in depressions.

Convulsive therapy does not prevent subsequent depressive episodes in the same patient. There is even some feeling that the shortening of a depressive phase by convulsive therapy also shortens the intervals between episodes. In such cases, antidepressant medication can be given. Where this is unsuccessful, a monthly preventive ECT has been shown to be an effective means to forestall future episodes in many cases.

Manic episodes. The manic reactions of a manic-depressive psychosis can also be treated successfully with ECT, although results are less reliable than in depressions. Therefore, it has been recommended that these patients be given 8 or 10 ECT on subsequent days. This may improve the outcome considerably more than treatment given in the usual three times a week routine.

Schizophrenia. This is still one of the most important indications for convulsive therapy, although ECT never has been very successful in chronic cases, where it has been replaced to a large extent by the neuroleptic drugs.

Acute schizophrenia. In acute schizophrenia, it often depends on the preference of the therapist whether he administers medication first or starts immediately with ECT. No rules have ever been established as to which procedure is preferable, and the decision depends mostly on such external circumstances as the time factor, hospital expenses, and the difficulty in controlling a disturbed patient.

Where successful ECT removes acute schizophrenic symptoms with 3 or 4 treatments, it is necessary, however, to continue treatment up to 10 and possibly up to 15 or 20 treatments because in schizophrenia, contrary to depressions, termination after the first removal of all symptoms almost invariably leads to a relapse within less than a week's time.

If neuroleptic drugs are given first and prove successful in removing symptoms, a hospitalized patient should not, in the writer's opinion, be discharged without temporary withdrawal of medication. One of the reasons for this recommendation is that many patients do not continue their medication once they are discharged from the hospital. The more important reason, in the author's opinion, is that in acute schizophrenia every attempt should be made to obtain a remission rather than mere symptom removal with need for continuous medication. Very often the drugs only cover up the symptoms, and at the moment of their withdrawal the entire psychopathology reappears, even after 2 or 3 months of successful medication. If this is the case, ECT should be instituted immediately because it is known that convulsive therapy is most effective during the 1st year of illness. Therefore, every patient should be given the opportunity to receive convulsive or insulin treatment during the favorable period of the 1st or 2nd year of illness. If by then he has not obtained a remission, neuro-

leptic drugs can still be given to maintain a certain degree of improvement as long as the patient is willing to take the drugs.

Statistics show that two prognostic factors are decisive in any group of schizophrenics treated with convulsive therapy. The acute onset of illness is the most favorable prognostic factor, compared with the unfavorable insidious onset of the disease. Duration of illness of less than a year is the other favorable prognostic factor. Many other prognostic factors, such as sex, age, and psychodynamic factors, have been investigated but without showing any convincing effect on the outcome.

Of the various subtypes of schizophrenia, catatonic excitement responds best. Although this group also responds well to neuroleptic drugs, ECT has been considered less dangerous in this group, called "pernicious catatonia" in the past, because these patients are easily threatened with vasomotor collapse when treated with drugs that have a hypotensive effect in themselves. In these catatonic excitements with severe agitation and frequent febrile temperatures, two or three ECT treatments given within 24 hours often have a life-saving effect. Catatonic stupors respond well temporarily, usually after two or three treatments, but the long term results in these cases are often disappointing. Acute paranoid schizophrenia in the younger age group also responds well to ECT. Paranoids in the middle-age group, often diagnosed "involutional psychosis, paranoid type," respond symptomatically but relapse easily, even after a long series of treatments. Simple and hebephrenic schizophrenics have the poorest results.

All this corresponds to the spontaneous prognosis of untreated schizophrenics, but reliable statistics have shown convincingly that the results with shock treatments, both convulsive and insulin, double the figures of spontaneous remissions in the various schizophrenic groups.

Chronic schizophrenia. In chronic schizophrenics, where pharmacotherapy has replaced ECT to a large extent, there are still some indications for maintenance ECT, given every few weeks. One example for such indication is a patient with catatonic stupor who tends to become more withdrawn every few weeks and who, like most withdrawn schizophrenics, does not respond to drugs. There are other schizophrenic syndromes with target symptoms for which present day drugs are ineffective. Patients unwilling to take regular medication represent another group in which such maintenance ECT may be indicated. A clear-cut statement that ECT is no longer indicated in chronic schizophrenia is therefore not warranted. Each case has to be judged on its own.

Psychoneurosis. Psychoneurotics do not represent a promising indication for ECT. Attempts made in the past turned out to be quite negative. The only exceptions are neurotics with depressive symptoms and those in whom acute anxiety or panic states can be

removed with one or two ECT treatments in a purely symptomatic way. On the other hand, neurotics are apt to react to the side effects of ECT such as memory impairment or some physical complaints in an exaggerated manner and sometimes even with gross hysterical manifestations. Therefore, few real indications for ECT in neurotic patients will be found.

Other disorders. Other psychiatric disorders will occasionally present an indication for convulsive therapy. Psychiatric patients with organic conditions, epileptics, and mentally retarded patients may have psychotic episodes that respond well to a few ECT treatments. Acute organic reactions such as toxic infectious psychoses also respond well, but here pharmacotherapy is usually preferable and adequate.

Psychosomatic conditions such as neurodermatitis and ulcerative colitis have also shown occasional improvement under ECT. The same is true for anorexia nervosa in individual cases. Therapeutic attempts with ECT have also been made in acute pain conditions such as trigeminal neuralgia and painful phantom limbs, and some good results have been reported. However, none of these conditions represents a definite indication.

Personality disorders have also been treated with ECT, but no convincing results have been reported. Convulsive therapy does not change the basic personality of a patient. It has its best results in those where an acute psychotic episode occurs in a previously healthy personality. This applies primarily to schizophrenics and the episodically occurring affective psychoses. Cases of pseudoneurotic schizophrenia or certain paranoid states that develop almost unnoticed in basically paranoid or schizoid personalities do not respond to convulsive treatment. Cyclothymic personalities with mood swings do not represent a good indication for ECT.

Mechanism of action. Convulsive therapy has no influence on the basic personality. This is one of the facts that must be taken into consideration when theories on the mode of action of convulsive therapy are discussed. Many such theories have been ventilated in the past, but no convincing theory is available. Neither psychological nor organic theories have any basis in clinical or laboratory findings. Therefore, we must admit that we are very successfully treating conditions of unknown cause with treatments of an equally unknown mode of action.

Suggested Cross References

A detailed comparison of the effects of the antidepressant drugs and electroconvulsive therapy is presented in Cole and Davis' section on antidepressant drugs (Section 35.2). For further information regarding specific uses of convulsive therapy, the reader is referred to the section on organic treatment of schizophrenia by Fink and Itil (Section 15.6) and to the sections on the following psychiatric disorders, for which convulsive therapy may be indicated: involu-

tional psychotic reaction by Ford (Section 17.3), psychotic depressive reaction by Huston (Section 17.2), neurotic depressive reaction by Mendelson (Section 24.2), and manic-depressive reaction by Cohen (Section 17.1). 35.6 INSULIN COMA TREATMENT

LOTHAR KALINOWSKY, M.D.

Introduction

History. As soon as insulin was discovered in the early 1920's, psychiatrists in various countries began to use it to improve appetite and weight of psychotic

patients. At the same time, it was noticed that insulin had a sedative effect, which was the second reason for its popularity among psychiatrists. Both for its sedative effect and for its weight-increasing effect, it was particularly useful in the treatment of morphine addiction. In a sanatorium near Berlin that dealt primarily with this type of patient, Manfred Sakel discovered what is known today as insulin coma therapy.

Sakel, like many others, applied subcoma amounts of insulin not only to morphine addicts but also to other psychiatric patients. Occasionally he saw insulin-sensitive patients go into a coma, which he at first considered an undesirable complication. It is to his credit that he recognized that some psychotics who developed such a coma came out of it in a remarkably improved mental state. This observation led him to work out a technique by which hypoglycemic coma was induced purposely. Sakel moved to Vienna and, with the help of the staff of the University Clinic there, reported on this new treatment for schizophrenia in 1933. The first report on a larger series of schizophrenics successfully treated was published in cooperation with Dussik, who, with Laqueur, is today one of the proponents of insulin treatment in the United States.

Present use. At present, insulin coma therapy is utilized in very few places throughout the world. This is very much regretted by everyone who has had experience with this treatment. It is undeniable that insulin treatment is cumbersome and not without dangers, although these have been reduced considerably in recent years. Administrators of psychiatric hospitals dislike the treatment, which is expensive and requires a large number of well trained psychiatric personnel. It was, therefore, understandable that, at the time of the introduction of convulsive therapy, insulin was temporarily neglected. When pharmacotherapy was introduced in the 1950's, insulin was abolished prematurely in many hospitals. There is a definite need for the continuation of this treatment, although perhaps one hospital in each area would be sufficient for a type of therapy for which not every hospital in the country can be fully equipped.

Technique

Early technique. Sakel's original technique consisted of the injection of increasing amounts of insulin, to the point where hypoglycemic coma would occur. In view of the possibility of an allergic reaction and, more important, hypersensitivity to insulin in individual patients, treatment is usually started with 10 or 15 units. This is increased each day by 5 or 10 units. A coma is usually obtained with 100 or 200 units. However, there are patients who show insulin resistance and need many hundreds of units to reach a hypoglycemic coma. On the other hand, there are also patients who reach coma level with very small amounts.

Patients with some insulin resistance sometimes reach a coma with smaller amounts when the zigzag method, recommended by von Braunmuehl, is used. Patients in whom 200 units do not produce a coma are given 30 units the next day and then returned to 200 units, this time achieving a deep coma. Various ways to alternate the dosage have been devised and must be left to the experience of the therapist.

Modifications. Modifications of Sakel's original technique are manifold. Two of them shall be mentioned here. At the Pennsylvania Hospital, Bond and Shurley routinely used higher doses. They began with 50 units and doubled this each day to 100, 200, 400 units. As soon as a deep coma was reached, they reduced the amount of insulin to determine the minimum coma dose. In the hands of the skilled therapist, this method apparently did not lead to untoward effects.

An opposite procedure, linked to the name of Laqueur, is the administration of multiple doses of insulin to reduce the amount necessary for a coma. He starts with 5 to 10 units and applies the daily amount in three divided doses in intervals of 15 minutes. Thus, he is able to obtain a coma in most patients with 60 or 70 units of insulin. The time required each treatment day with this technique is longer because the patient receives his insulin earlier and goes into coma later than with the other techniques.

Manifestations

Approximately 1 hour after the injection of insulin (which in Sakel's technique is given at 7 A.M.) the patient shows the first signs of hypoglycemia—feelings of tiredness and somnolence and perspiration.

During the 2nd hour, the patient's sensorium becomes clouded, and he falls asleep. Some may become restless, toss around, and yell. Others are disoriented or show hallucinations, which are often different from those due to their illness. Patients who never hallucinated before may develop hallucinations during the state of hypoglycemia. The speech becomes dysarthric. Aphasia and apraxia may be noticed. The motor phenomena during the 2nd hour consist of automatic movements, forced grasping, myoclonic twitches, and various dystonic manifestations. Different schemes have been developed to show the disintegration of brain functioning according to various levels, defining symptoms due to suppression of cortical activity, release of basal ganglia, release of the midbrain and finally of the medulla oblongata.

A not infrequent occurrence is convulsions, mostly observed during the 2nd hour of hypoglycemia. At first, they were considered a complication. Later on, they were regarded as a desirable manifestation. Actually, they are an undesirable feature, though not a complication. Patients who are inclined to have convulsions often receive anticonvulsant medication prior to the insulin injection. It is also customary to terminate the hypoglycemia when a convulsion has

occurred, although it can be questioned whether this is really necessary. Convulsions are also frequent during the later hours of hypoglycemia. At this time, status epilepticus may occur. These late convulsions are considered a danger sign and require immediate termination of hypoglycemia.

During the 3rd hour, the patient can go into a true coma. The coma stage is reached when the patient is unable to respond to stimuli of various kinds. The deepest coma is reached when the patient no longer responds to painful stimuli with a needle or to supra-orbital pressure. At this stage, spasms similar to those of decerebrate rigidity may occur, the pupils do not react to light, and the deepest or so-called midbrain stage is characterized by a change of the pupils from dilation to miosis, absence of the corneal reflex, and disappearance of tendon reflexes. It is this stage that is, on the one hand, considered most effective and also, on the other hand, a definite danger sign, one to be avoided by less experienced workers. At first the patient is usually left in coma not longer than 15 minutes; in subsequent treatments, the coma can be slowly prolonged up to 1 hour. Attempts to leave the patient in this deep coma for several hours were made in the past but remained experimental.

Termination

Hypoglycemia was originally terminated by administration of a sugar solution through nasal tube feeding. If this was unsuccessful, and the patient was not awake after 20 minutes, intravenous glucose was given. Intravenous termination received second place because the 33 or 50 per cent glucose solution easily leads to coagulation in veins that may be needed for emergency measures. Today, termination is simplified by the discovery of the hormone glucagon, which can be used in doses of 0.33 mg. to 1 mg. intravenously or intramuscularly.

Awakening usually begins after 10 or 20 minutes, after which time, if the patient does not react, the dose should be repeated. Small amounts are usually sufficient to awake the patient to a point where he is able to drink a sugar solution or other carbohydrate preparation. Laqueur also found adrenalin and thiamine to be effective in many patients for termination of hypoglycemic coma.

After-effect. A so-called after-shock may appear several hours after termination of treatment. The patient may perspire or just feel tired and lie down for an after-lunch nap. He should be watched carefully because such patients, unnoticed by the nursing personnel, may not be asleep but actually in a second hypoglycemic coma. Patients should have some sugar with them and be told to eat some at the first sign of uneasiness. They should be warned against sleeping in the afternoon of treatment days and should be engaged in group activities so that they can be watched. If a second coma develops, the usual measures of termination have to be undertaken.

Number of Comas

The number of comas is usually determined by the response of the patient in his psychiatric symptoms. Contrary to convulsive therapy, the improvement in insulin treatment occurs more slowly; therefore, treatment should be continued to the point of maximum improvement. Forty to 60 comas are considered a minimum. It should be pointed out here that only the actual number of coma days is being counted. After the patient has reached his optimal improvement, a few more comas should be given.

Recently, the insulin units in Vienna (Arnold) and in the Creedmoor State Hospital (Laqueur) have shown independently that larger numbers of comas are desirable. Both units reached figures of 100 and more comas, which means series of 4 to 5 months' duration, even if treatments are given six times a week. Most units only give five treatments a week. Although this extension of the treatment period makes insulin coma treatment even less applicable in many hospitals, it demonstrated convincingly that insulin coma is a most effective treatment if applied adequately.

Complications and Contraindications

Cardiovascular complications. Two types of complications stand out in any report on insulin coma treatment. One is that of cardiovascular complications. Changes in pulse rate are normal manifestations in hypoglycemia. Complications can be due to acute cardiac insufficiency in patients who have an unrecognized cardiac illness or due to sudden vasomotor collapses. In an individual case, it is often difficult to decide what has led to a cardiovascular complication. Proper management of the first signs of cardiac dysfunction and early recognition of such a complication are paramount.

Protracted coma. The most important and most frequent complication is the protracted coma. These protracted comas are actually not prolonged states of deep hypoglycemia but rather encephalopathies. The patient remains in coma after the hypoglycemia is eliminated by means of glucagon or repeated intravenous glucose administration and even after abnormally high blood sugar levels are obtained.

The most important treatment for this emergency consists of prevention, although, even in well organized insulin units, this complication occurs. Laqueur claims that his technique with divided doses practically eliminates protracted comas. Once it has occurred, no specific therapeutic measures are available. It is important that the vital signs of the patient be maintained, as in any other coma of whatever origin. Transfusions, vitamin injections, and many other measures have been recommended. Today it is recognized that all those techniques that anesthesiologists use in patients in deep states of unconsciousness should be applied, particularly adequate oxygenation and all measures to maintain cardiovascular activity.

Fatalities. Fatalities in insulin coma treatment were originally reported as 0.5 per cent of patients treated. This figure would be lower in highly specialized units. Considering the seriousness of the mental illness treated, this was not regarded as unduly high, and it seems that modern techniques have reduced considerably or even eliminated the number of fatalities.

Psychiatric manifestations. Psychiatric manifestations seen during insulin treatment are often difficult to interpret. An activation of the psychosis may occur, but probably more frequent are short-lasting organic reactions, which may follow protracted comas. Permanent organic brain damage may occur but is extremely rare in treatments not complicated by protracted coma. The psychotic symptoms for which the patient is being treated may disappear for a short while after the awakening of the patient. These symptom-free periods may extend to hours and finally lead to complete disappearance of symptoms in cases with favorable outcome. These periods may be used for attempts at individual psychotherapy. Such combinations of organic insulin therapy, and psychotherapy, both individual and group psychotherapy, have been frequently recommended.

Neuropathological changes. Such changes due to hypoglycemia have been found both in animal studies before and after the introduction of insulin coma treatment for schizophrenia and in patients who died under treatment. Most changes are reversible, but there are a few irreversible cell changes and areas of rarifications. The morphological alterations according to Ferraro and Jervis may be of vascular as well as cellular origin.

Contraindications. There are more contraindications in insulin coma treatment than in convulsive therapy. Any patient with cardiovascular pathology should be excluded from this treatment. It is for this reason that patients over 50 years of age are rarely accepted for insulin treatment. The same is true for patients with renal, respiratory, and other general medical diseases. Diabetes is not necessarily considered a contraindication, although this point is controversial, as Horowitz does consider diabetes to be a contraindication.

Pregnancy is a condition in which insulin should be avoided if possible. Although no damage to mother or child has ever been reported in convulsive therapy, there is some evidence that the fetus may be damaged in insulin treatment during the first months of pregnancy, although the findings are not really conclusive.

Indications and Results

Insulin coma treatment was considered by Sakel to be a new physiological treatment for schizophrenia. Although his theoretical explanations regarding its effectiveness did not withstand criticism, schizophrenia remains the main indication for this method. Large statistics have shown that the figures for spon-

taneous remissions can be doubled with the help of insulin treatment. There are many statistics that show lower or higher figures of favorable outcome, but usually methodological errors, inadequate numbers of treatments, or inadequate depth of comas can be demonstrated when figures deviate from those published by internationally known insulin centers.

In an individual case, the decision as to whether insulin or other treatments should be applied has varied with the times. In the 1940's, insulin was considered the treatment of choice in all cases of schizophrenia. In practice, however, electric convulsive therapy, being the simpler method, usually received preference. Only when electric convulsive therapy had failed was insulin, or insulin combined with convulsive therapy twice a week during the insulin comas, applied.

Insulin and Convulsive Therapy

Combined insulin and convulsive therapy has been used quite extensively and has become so much a routine in insulin units that a clear evaluation of insulin coma treatment alone has hardly ever been made since convulsive therapy became available. Both Metrazol and electrically induced convulsions are used, mostly when the patient is in deep hypoglycemic coma and shortly before he is awakened. Originally, convulsions were induced to achieve faster suppression of unpleasant schizophrenic symptoms. The slow clinical effect of insulin treatment suggested additional convulsive treatments, which later became a routine in many, though not all, insulin centers.

Summary

After the introduction of pharmacotherapy, all shock treatments, both convulsive and insulin, were neglected for a while. After it became obvious that the older treatments are indispensable, the more easily applicable electric convulsive therapy was soon reintroduced. Many insulin units were discontinued, and the unavailability of trained personnel is an inhibiting factor in the revival of more extensive use of insulin therapy.

Many of those who have had experience with all somatic treatments are deeply convinced that there is a considerable number of schizophrenic patients for whom insulin is the only treatment that leads to a true remission.

Furthermore, it has been the clinical experience of many that the quality of an insulin remission is superior to that achieved with any other treatment. It must be deeply regretted that comparative studies with matched groups of patients are not available. As long as this is the case, the clinical experiences of those familiar with all available treatments must be the guide line. Many of these feel strongly that insulin coma treatment should not be eliminated from our therapeutic armamentarium.

35.7 MISCELLANEOUS ORGANIC THERAPIES

LOTHAR KALINOWSKY, M.D.

Today some of the somatic treatments discussed in this section are of historical interest only. They include bloodletting, emetics, and purgatives. In more recent times, new concepts in general medicine have often been applied to psychiatry. When they have been found to be ineffective, they have been abandoned. An example is the concept of focal infection as the cause of many illnesses. It led to operations on tonsils, teeth, and other sources of infections. With the advent of serology, vaccines, autovaccines, and sera of recovered schizophrenics have been developed.

More important were efforts to apply endocrinological knowledge to the treatment of psychiatric disorders. Every step of progress made in this field led to new applications of hormones. Both thyroid deficiency and hyperthyroidism were accused of contributing to mental illness, and treatments were based on their correction. The latest attempts are experiments with the adrenal glands. Bilateral adrenalectomies have been performed in schizophrenics, with incon-

clusive results. Adrenocorticotrophic hormone and cortisone were recommended by some, but their value was disproved by others. Endocrinological studies continue on psychotics, with the hope of therapeutic usefulness.

Some organic methods have had wider application and will be discussed separately here.

Continuous Sleep Treatment

In 1922, the Swiss psychiatrist Klaesi introduced a method of prolonged sleep by means of drugs with narcotic action. Various drugs and their mixtures were used, with particular preference given to chloral hydrate, paraldehyde, and barbiturates. Patients were kept in a sleeplike state for 10 days or longer. The unconscious state was reduced only temporarily for feeding and excretion of feces and urine. At the end of the treatment period, medication was reduced slowly in order to avoid convulsions or a delirium-like psychosis, which may follow sudden withdrawal.

Results were favorable in a variety of psychiatric disorders. Klaesi stressed the psychological aspect of this treatment, emphasizing psychotherapy at the time the patient wakes up and is looking for help. Psychotherapy itself has been found to be facilitated by this treatment. Others, however, consider it a purely organic treatment.

Since the introduction of the various shock treatments, it is rarely used with psychotics, but it is still used extensively in the treatment of more acute neuroses, such as the war neuroses, for which it was particularly used in England. Based on Pavlov's concepts, sleep treatment is still being used widely in the Soviet Union, but in most other countries the introduction of neuroleptic drugs eliminated the application of sleep treatment. In some psychiatric centers the phenothiazines are combined with barbiturates for a sleep treatment of several days or weeks.

Acetylcholine Treatment

In 1937, Fiamberti recommended acetylcholine as a less drastic method of shock therapy. Its intravenous injection causes cardiac arrest for 30 to 50 seconds and unconsciousness of short duration. Injections of up to 600 mg. were used on schizophrenics. Lopez Ibor used smaller amounts of up to 200 mg. in anxiety neuroses.

In this treatment of psychoneuroses only slight respiratory difficulty, coughing, and slow pulse were noticed, and repeated intravenous injections were considered valuable by observers in various parts of the world. Both psychological and organic explanations were given for favorable results of this method in neurotics.

Carbon Dioxide Therapy

In the 1920's, carbon dioxide was used in the treatment of psychotics, but it was abandoned when the shock treatments were introduced. In 1947, Meduna started treating psychoneurotics by having them inhale

a mixture of 30 per cent CO₂ and 70 per cent O₂. Twenty to 25 respirations were recommended. By that time, the patient had usually lost consciousness. A smaller number of respirations without loss of consciousness has also been tried. The number of treatments was set at 20 or more.

Good results were obtained in patients with conversion symptoms, anxiety neurosis, personality maladjustment, and emotional instability. Stutterers represented an especially favorable group. The method proved to be ineffective in obsessive-compulsive neuroses and hypochondriasis.

There are many contraindications, such as hypertension and cardiovascular disease.

The treatment was based on the theory that psychoneurosis is due to an abnormally low threshold of stimulation with respect to normal stimuli. The treatment is intended to raise the threshold of stimulation to the normal resistance to noxious stimuli, such as carbon dioxide. Meduna emphasized the value of this method as a purely organic one, but others stressed the need for simultaneous psychotherapy.

For a while, CO₂ was widely applied by psychiatrists and even some nonpsychiatrists. However, it is unpleasant for the patient and not without danger in persons with unrecognized cardiac or pulmonary conditions. It soon lost its popularity and is seldom used today.

Lithium Therapy

Lithium salts have found a wide application in some countries (particularly England and Scandinavia) for the treatment of psychotic excitement, especially in manic patients. Lithium carbonate, 0.6 gr., t.i.d., or lithium citrate, 1.2 gr., t.i.d., are given, preferably after meals to avoid gastrointestinal disturbances, which are often a serious handicap in the proper application of lithium therapy.

Contraindications are renal conditions and decompensated heart disease.

This treatment is particularly effective in those patients with frequent manic episodes. If the patient is able to continue the medication, it seems to have a considerable preventive value for future episodes of both manic and depressive types.

Atropine and Scopolamine Therapy

Toxic doses of atropine sulfate, injected intramuscularly, were recommended by Forrer in 1951. Aside from various vegetative symptoms, restlessness and delirious states can be observed. They are followed by a coma with spontaneous awakening.

The treatment was primarily given in neuroses, but it also seemed to be effective in excitement states of various diagnostic categories. Hyperthermia was the most dreaded complication.

Recently Goldner, in the same hospital as Forrer, recommended scopolamine sleep treatment as a new nonconvulsive method leading to states of uncon-

sciousness. After a period of 4 to 6 hours of coma, the patient wakes up in a confused state, showing various organic reactions including visual hallucinations.

The doses of scopolamine range from 5 to 30 mg. initially and are increased to a maximum of 100 mg. Schizophrenic and other patients have been treated, partly in combination with psychotropic drugs.

Therapeutic Attempts Based on Metabolic Findings

Historically, the studies by Gjessing regarding nitrogen metabolism in schizophrenics with a periodic course of the disease led to the first attempts to influence nitrogen metabolism in schizophrenics for therapeutic purposes. He combined dietary measures with thyroid extract. Other attempts were made in manic-depressive psychoses in connection with observations in cholesterol metabolism. Adrenal cortex preparations were used to correct this metabolic disturbance. Others tried to explain exacerbations in schizophrenia with impairment of liver function and used a diet poor in fat and rich in carbohydrates and proteins.

All these attempts turned out to be unrewarding, but the hope for the future is based on the idea that attempts and findings in this direction will eventually explain the cause of the psychoses and consequently lead to an answer to the question of treatment. More recent findings of protein metabolites in the blood of schizophrenics may be stepping stones in this direction.

Other attempts of this nature were based on observations made in work with the shock treatments. When acidosis was found to accompany convulsive therapy, it was hoped that this might be the effective agent in this method. Acidifying drugs and dietary measures producing acidosis were tried. Delay combined ketogenic diets with acidifying drugs.

Another attempt based on the convulsive therapies was made by Cerletti. He produced electric convulsions in animals and extracted a substance, which he called acroagonine, from the brains of the animals. He hoped that this substance would contain the effective agent in electric convulsive therapy. Results remained unconvincing.

However, all such attempts to utilize various research findings should be supported, in the hope of arriving at a more effective treatment of the psychoses.

Suggested Cross References

See Cohen's section on manic-depressive reaction (Section 17.1) for further discussion on the use of lithium therapy.

35.8 PSYCHOSURGERY

MILTON GREENBLATT, M.D.

History

In 1935, Fulton and Jacobsen demonstrated that monkeys with frontal lobe extirpations could remember old tricks, learn new ones, and accept frustration with philosophical calm. On the basis of these pioneer research studies, Moniz and Lima, in Portugal, severed frontal lobe white tissue in 20 psychotic patients and reported promising results in terms of reduced tensions and decreased psychotic disorganization. In the United States, Lyster attempted to use this technique in the treatment of involutional psychoses. However, the concept and techniques of lobotomy were not investigated intensively until 1942, when Freeman and Watts reported that mental distress, e.g., depression, worry, and agitation—and even hallucinations at times—could be greatly alleviated by sectioning frontal lobes in a coronal plane. Freeman observed a degeneration of medial, dorsal, and anterior thalamic nuclei following the operation, and he assumed that severing the connections between the thalamus and frontal cortex interrupted or reduced the intensity of the emotional charge imparted to abnormal ideation.

The treatment of chronic psychotic patients by frontal lobotomy, or leucotomy, spread throughout the world, and for a time this was the treatment of choice in such cases. As might be expected, its use has been sharply curtailed since the discovery of tranquilizers and the use of various rehabilitative measures designed to improve the patient's interpersonal relationships and his functioning in the community. Nevertheless, lobotomy is still advocated in many treatment centers for refractory chronic patients, and good results have been reported over the long term. Still lacking, however, are conclusive comparative studies on the relative effectiveness of psychosurgery, as opposed to nonsurgical modalities, in the treatment of chronic psychiatric illness.

Psychosurgical Procedures

A great variety of surgical procedures have been explored in an attempt to produce the most favorable mental changes with the smallest possible lesions,

most strategically placed. The methods described herein, which are generally considered among the more significant techniques, may be further clarified by reference to Figures 1 and 2.

Full bilateral lobotomy. Moniz used a superior approach and cut four to six cores of white matter in each frontal lobe, using a wire-looped "leukotome." Freeman and Watts, using a lateral approach, severed white matter in a plane anterior to the anterior horns of the lateral ventricles. Earlier, Lyster had used the superior approach advocated by Moniz and Lima, but he had added the element of an "open operation" (i.e., operating under direct vision). Poppen and his colleagues have used the "open operation" extensively since 1943.

Bilateral orbital lobotomy. Dax and Radley Smith have experimented with leucotomy at various levels of the frontal lobes, and they ascribe special merits to lower or orbital sections, particularly for depressed patients who are passive and apathetic. Recently, on the basis of a follow-up study of 350 patients over a 10-year period, Sykes and Tredgold have stressed the value of restricted orbital undercuttering.

Bilateral transorbital lobotomy. Introduced by Freeman, this technique is carried out without benefit of specialized surgical techniques. A pointed instrument is thrust through the orbital plate and then moved through a plane calculated to sever the anterior white fibers. For the most part, Freeman has restricted the bilateral transorbital lobotomy to patients in the early stages of schizophrenia; favorable results have been reported for this patient population.

Livingstone, Ltd. *Diagram 1*, A, Scoville's orbital undercutting; B, Scoville's undercutting of superior convexity; C, Grantham's electrocoagulation of inferior medial quadrant; D, Spiegel and Wycis's stereotaxic electrocoagulation of thalamic nucleus. *Diagram 2*, A, Scoville's cingulate gyrus undercutting; Livingston's cingulate gyrus subcortical sectioning; B, Freeman and Watts's "closed" standard lobotomy; C, medial inferior quadrant section by McKenzie's leucotomy method, Schwartz's nasal speculum method, Grantham's electrocautery method, and Poppen's direct vision suction and spatula method. *Diagram 3*, A, Poppen's "open" standard lobotomy under direct vision; B, Freeman's transorbital lobotomy; arrows indicate deep frontal cut; C, Pool's topectomy operation.

Bilateral topectomy and cortical undercutting.

In a small but well studied series of cases, the Columbia-Greystone Associates removed portions of frontal cortex of 15 to 30 gm. While the results of topectomy seemed promising initially, later follow-up study demonstrated that the improvement of the patients in the experimental group did not exceed that of the control group.

Scoville has been the principal proponent of cortical undercutting (see Figure 2), especially areas 9 and 10, leaving the cortical flap in situ. He has also undercut the cingulate gyrus in the orbital cortex, using a similar technique, and has reported results equal (if not superior) to more conventional techniques.

Bilateral thalamotomy. This technique was developed by Spiegel. Using stereotaxic methods, he co-

agulates specific thalamic areas in an effort to relieve mental distress in psychiatric illness, on the one hand, and intractable pain caused by physical illness, on the other. Unfortunately, this method may present a greater risk, as compared to other techniques.

Bilateral cingulectomy. Livingston has reported high anatomical accuracy, low surgical risk, and satisfactory therapeutic results with bilateral cingulectomy.

Bimedial lobotomy. Greenblatt and Solomon and their associates have experimented with medial frontal leucotomy, and they claim that this technique is superior in terms of preservation of personality, and limitation and reduction of "blunting." Initiative and emotional responsivity, in particular, seemed to be better preserved in patients who had bimedial lobot-

omy, as compared to those cases on whom full bilateral lobotomy was performed.

Bilateral inferior medial lobotomy. A number of surgeons favor the use of inferior medial area destruction. Grantham, in particular, has done electrocoagulation in this area, using a fine needle in order to produce minimal damage to cortex. As a result, the incidence of postoperative seizures was greatly reduced in the patient group studied, and personality remained unimpaired for the most part; at the same time, psychiatric symptoms were alleviated.

Unilateral lobotomy. Lyerly and his associates at the Boston Psychopathic Hospital have performed unilateral lobotomies (right or left). Their results indicate that, while some personality changes of a favorable nature occur, the personality changes produced are less satisfactory than those produced by bilateral procedures, and that, in general, this method is less reliable.

Sonic destruction. Finally, Lindstrom, using ultrasonic beams, produced cortical destruction with cell fallout, but without gliosis. This procedure lessened the incidence of postoperative epilepsy, as compared to conventional destructive cortical techniques.

Indications

In recent years, there has been a tendency to utilize limited surgical procedures at an earlier stage of psychiatric illness. Nevertheless, the overriding consideration for most psychiatrists is that lobotomy produces an irreversible destructive brain lesion. Consequently, it is prescribed with great caution; in fact, usually, lobotomy is not recommended until all other methods have failed. To counteract this prevalent negative attitude, it should be emphasized at the outset that, while lobotomy is a critical event in the life of the patient, it need not be the final event. After psychosurgery, other treatments, including the phenothiazines, milieu therapy, and psychotherapy, may become more effective. If all the available treatment procedures, i.e., psychotherapy, somatic therapy, pharmacotherapy, milieu therapy, have been given an adequate trial, and there has been no remission of the illness after a period of 2½ to 3 years, the psychiatrist must consider the possibility that the patient may have to be hospitalized for a very long period or even spend the rest of his life in a mental institution. Under such circumstances, a recommendation of lobotomy would certainly seem justified. Again, in the case of an affective psychosis, psychosurgery should be considered if the disorder has interfered with the patient's functioning over a period of years.

From the standpoint of symptomatology, lobotomy is indicated, in particular, for patients suffering from severe tension, which stems from fear, worry, depression, anxiety, agitation, or all of these in combination. Accordingly, schizophrenic patients who manifest such tension, which arises, in part, from their aware-

ness of, and efforts to struggle with their problem, are the best candidates for psychosurgery.

For maximum effectiveness, attention must be given not only to the selection of suitable patients, but also to the selection of an appropriate surgical technique. In addition, a cooperative family is an important criterion of eligibility for psychosurgery. Patients from families which are warm and accepting, and who maintain close ties with them, fare better than others. As for the type of operation, patients whose illness is less severe will require less extensive surgery. In fact, in general, there has been an increasing tendency to limit operations to the medial and inferior aspects of the frontal lobes.

Complications

Neurological. The risk to life is small; most recent surgical reports estimate mortality at well under 1 per cent. However, parasurgical necrosis may occur, especially if suction techniques are used. And numerous cysts may develop in, and around, the plane of section. Morbidity also includes hemorrhage and convulsive seizures. The latter have occurred in 15 to 20 per cent of the cases which involved bilateral cortical damage, and have been correlated with preexisting brain damage, extensive preoperative electric convulsive therapy, and immediate postoperative sepsis or infection at the operative site. However, seizures are usually few in number and readily responsive to anti-epileptic medication. Nevertheless, Raskin has suggested that in some cases, at least, there may be progressive pathological changes for years. Certainly, electroencephalographic changes may continue for a period ranging from months to years.

Physiological. There have been reports of incontinence and of excessive appetite, particularly in patients who have had the conventional full bilateral lobotomy.

Psychiatric. The patient's social behavior may be tactless and crude. Lack of insight and psychopathic behavior have also been reported. However, careful studies have not revealed an alarming incidence of postoperative alcoholism, sexual acting out, or criminal behavior. In any event, certainly the tendency of these patients to engage in such behavior is no greater afterward than it was before the operation.

Psychological. The psychological functioning of lobotomized patients has been studied extensively. No serious decline in I.Q. has been noted. However, some impairment of the capacity for concept formation and planning has been reported, and patients tend to make impulsive decisions without prior deliberation. These deficiencies are more marked when the operation is performed to relieve intractable pain in a patient who is relatively intact intellectually. In contrast, the thinking processes of some psychotic patients have been so crippled by their mental disorder that they often achieve a higher performance level on

intellectual tests after lobotomy, despite the very considerable brain destruction.

Results of Treatment

Anatomical sequelae. Even when the operative procedure of lobotomy remains constant, inevitably, there will be considerable variation in plane and extent of damage, concomitant with the variation in skulls, brains, and, presumably, in functional localization. A large number of tracts may be cut, including long tracts from the frontal to the posterior cortical areas, and shorter ones to the pons, hypothalamus, and temporal areas (uncinate fasciculus). Many thalamofrontal projections are severed, including, in particular, projections from the dorsal, medial, and anterior nuclei. The anterior horns and the lateral ventricles are widened. Circulation of the frontal areas is reduced.

McLardy and Meyer have postulated a definite quantitative relationship between the degree of personality change and the amount of prefrontal cortex sacrificed. More severe personality damage occurs with bilateral involvement of ventral and central segments of frontal lobes. Similarly, Yakovlev et al. have stressed the fact that widespread disorganization and subsequent reorganization of brain function necessarily follow massive frontal cutting. However, a valid anatomical explanation for this phenomenon is not yet available.

Personality changes. As mentioned above, more extensive personality change and functional loss are produced by large area destruction than small area destruction, by posterior sections than anterior sections, by bilateral than unilateral procedures. It follows, then, that procedures such as bimedial or orbitomedial lobotomy, or cingulectomy, which produce smaller lesions, may also alleviate emotional distress to a considerable extent, without adversely affecting the patient's psychological functioning. Actually, it is difficult to predict the outcome of lobotomy with any degree of accuracy. However, a survey of the findings presented in hundreds of reports might be summarized as follows.

Motivation. Drive is often reduced. Lack of initiative, laziness, and apathy are particularly evident

in the immediate postoperative period, with considerable improvement over time. Ambition and goal-directed activity may diminish. In contrast, some patients, particularly those who were less disorganized prior to surgery, e.g., those with obsessive-compulsive or anxiety states, may take up life with renewed vigor. And, in schizophrenics, a reduction of the "drive" attached to hallucinations and other abnormal ideation may be therapeutically beneficial.

Self-concern. Anxious self-preoccupation, depression, and self-consciousness are predictably relieved after lobotomy.

Social behavior. The patient becomes more aware of his environment, is able to interact socially with his peers, particularly if he is encouraged to do so, and even seems to seek out and enjoy the company of others. In brief, the patient becomes more of an extrovert; unfortunately, however, as mentioned earlier, his behavior is often characterized by tactlessness and lack of refinement, particularly if the operation produced extensive lesions.

On the other hand, there is better integration of ego functions, and the patient's contact with reality is strengthened. Finally, he is less distracted by hallucinations, delusions, and suspicions which, in fact, may disappear entirely in time.

Affect. Perhaps because the patient's depression, anxiety, and agitation are greatly relieved, his feelings have less depth. Thus, while they may seem to be emotionally charged, they cannot be sustained. To illustrate, the patient may suddenly flare up in anger, but his anger will be forgotten just as quickly.

Prognosis. Patients whose illness is of shorter duration respond better than do those with an illness of long duration. Rapid onset of illness is a more favorable prognostic sign than insidious onset. Adults respond better than do children. (In fact, the operation is contraindicated in children.) Patients with some life achievement, e.g., job, education, marriage, children, do better than do those who have never attained these goals. Patients with a "healthier" preoperative personality organization are better prospects than those whose personality is less integrated. Patients with tension (as opposed to those who are apathetic), emotional responsiveness, insight, friendliness, and a tendency to verbalize, do better than patients without these qualities. Patients with a diagnosis of psychoneurosis, hypochondriasis, or obsessive-compulsive disorder, and those with severe depression and anxiety states fare better than patients with a diagnosis of schizophrenia (unless considerable tension can be detected, despite the patient's disorganized state) or chronic mania. Finally, as mentioned earlier, patients whose families are interested in their welfare, who are eager to cooperate, and who wish to make a place for them have a better prognosis than patients whose families have excluded them.

Long term follow-up. The literature has repeat-

TABLE I^a

Follow-up Study of the Work Adjustment of Chronic Psychotic Patients after Bimedial Lobotomy

	Preoperative	1 Year Postoperative	5 Years Postoperative ^b
"Good" work adjustment...	2 (6%)	12 (34%)	19 (54%) ++
"Fair" work adjustment...	8 (23%)	12 (34%)	4 (12%)
"Poor" work adjustment...	24 (68%)	11 (32%)	12 (34%) +

^a Table adapted from Paul, N. L., Fitzgerald, E., and Greenblatt, M. Five year follow-up of patients subjected to three different lobotomy procedures. *J. A. M. A.*, 181: 815, 1956.

^b Each plus indicates one deceased patient.

edly stressed the fact that good postoperative results may be sustained for many years; moreover, although improvement is slow, sometimes it is progressive over years. This is important because current reports indicate that improvement is not well sustained in other organic modalities, such as insulin coma treatment and electric shock. However, long term studies on comparable patient samples treated by comparable methods are not yet available.

Table I indicates the results of a long term follow-up study of the work adjustment of a group of chronic psychotic patients (mainly schizophrenic) who had a bimedial lobotomy. Only 2 per cent of the patients studied had a good preoperative work adjustment; that is, were working full time and productively; but 1 year after the operation 34 per cent were considered to have a good work adjustment. The number of patients with poor work adjustment decreased postoperatively but then remained essentially unchanged for 1 to 5 years.

Contributions of Psychosurgery to Psychiatry

First and foremost, lobotomy has demonstrated that chronically ill psychiatric patients have considerable residual potential for improvement. This, in turn, has challenged psychiatrists to reexplore vigorously other means of helping such individuals and to develop new therapeutic methods.

Second, the "lobotomy era" has added new impetus to research efforts to localize function in the brain and the frontal lobes. Indeed, current research involving electrode implantations and stimulation of limited zones has greatly enhanced our understanding of the role of the brain in health and disease. The neurological approach to psychiatric disorders has thus been strengthened. Admittedly, no single unitary theoretical conceptualization has received universal acceptance. However, many theoretical formulations have been proposed, and most of the old hypotheses concerning frontal lobe functioning have been rigorously scrutinized.

Finally, psychosurgery has greatly augmented the hope that, one day, our accumulated knowledge of the relationship between brain, personality, and mental disorder will constitute an exact science.

Chapter 36

Milieu Therapy

36.1 THE HOSPITAL AS A THERAPEUTIC COMMUNITY

EDWARD STAINBROOK, Ph.D., M.D.

Introduction

Several years ago, the President's Commission on Chronic Illness suggested that it might be useful to consider the theory and practice of medicine as a branch of the larger, more inclusive science of human ecology. This recommendation is particularly relevant to the understanding and treatment of behavioral disorders and of behavioral impairment in general. More precisely, the older medical model of physical illness as the symptomatic manifestation of the malfunctioning of a specific organic system cannot be fruitfully applied to the etiology of impaired behavior. A good deal of distressed human behavior—whether episodic, recurrent, or chronic—is the result of faulty social learning which has interfered with the individual's adaptive capacity and his ability to cope with life's vicissitudes. Much impairment is a reaction to distortions in the individual's present relationship to persons, ideas, and things; and some present impairment is a consequence of his perception, distorted or accurate, of the future. Hence, the use of the social system and culture of the hospital for the restitution of previously acquired learning and resources and the facilitation of new social learning constitutes a way of treating such impairment.

Definition. The designations milieu therapy and therapeutic community are used, therefore, in psychiatric hospital practice to refer to those aspects of the society and culture of the ward or hospital which may be influential in reducing the behavioral disturbances of patients. Behavior may improve because the environment is structured to provide human relationships which satisfy emotional needs, to reduce psychological conflict and deprivation, and to strengthen impaired ego functions.

Theoretical Orientation

When a patient enters a hospital, he adapts to and is integrated into the social structure and operation, both formal and informal, of that specific institution. And events within the hospital society, even though remote from that particular patient, may affect not only his psychological functioning, but his biological functioning as well.

A simple formula proposed by Theodore Sarbin may help to clarify the nature of the transactions between the patient and the hospital community. Behavior equals the characteristic self, plus the social role the individual is enacting at any given time. More precisely, every behavioral event is governed, in part, by the expectations, values, intellectual adequacy, and executive resources which characterize particular social role enactments. It follows, then, that a clear differentiation between self-action and role-determined action is crucial to the understanding of the individual's total behavior. Otherwise, as is so often the case, particularly in psychiatric hospitals, attempts are made to explain the patient's behavior entirely in terms of his self-dynamics. In that event, the significance of environmental factors, i.e., the conditions imposed by the hospital's social system, as an equally important determinant of behavior, is overlooked.

Therapeutic Principles

General considerations. Two basic considerations, therefore, are of primary concern in the administration of the psychiatric hospital. First, there must be an awareness of the fact that the social structure and process of the hospital may exert an unfavorable influence on the behavior of its patients, and on the relationships among staff members, which, in turn, will affect the administrative and therapeutic transactions of the organization. Second, on the basis of this realization, social action within the hospital must be structured so that the needs of both patients and staff are fulfilled; so that individual capacities for perceiving, differentiating, and interpreting a wide range of "constructive" experiences are stimulated, enhanced, and

developed. Finally, the structure of the hospital's individual and group therapy programs and its milieu therapy program, in particular, must derive from the concepts of developmental sociology. And concomitantly, these various therapeutic programs will focus on the restoration and development of each patient's unique potentialities.

Staff. In view of these concerns, it will be recognized that the therapy of the milieu is considerably more inclusive than the prescriptive direction of the ward personnel by a team leader, whatever professional role such a leader may occupy.

In relation to each individual patient, everyone in contact with him should ideally be able to answer clearly for himself the question, "What sort of human experience does this patient need with me now?" This is the final common pathway for the helping impulses of the therapeutic community. But some important determinants of this transmission may reside in the more comprehensive social system in which the ward transactions are embedded, such as, for example, the parallel administrative structure in a hospital of nursing services and medical staff. This may be a parallelism which may prevent effectively the operating autonomy of the ward as a socially articulate, unambiguous, coherent, and therapeutically dedicated unit. And this may be so even though the nurses and doctors in the ward group have committed themselves locally to each other as a team.

Patients. In more specific terms, the structuring and moderation of the social role the patient will enact and experience during his stay in the hospital society is the fundamental task of milieu therapy. The Cummings, in their recent book *Ego and Milieu*, have delineated the various therapeutic benefits which may derive from this approach. First, once the psychologically impaired patient has adopted a specific social role and it is reinforced by the complementary role action of the staff, these transactions serve to provide the patient with a stable, lucid environment. Second, the patient's own behavior is mirrored back to him. Third, the patient is offered responsible participant involvement in the human relations and administrative decisions of the ward community. By having delegated to him many of the tasks involved in communal living, he is provided the opportunity for the repair of performance, social adequacy, self-esteem, and human interaction and for the development of new behavioral resources.

Environment. As mentioned above, the provision and maintenance of a lucid environment will depend primarily on the nature of informational and communicative transactions within the hospital. More specifically, however, the psychological determinants of a lucid environment are the patient's awareness of self, of others, and of the reality which surrounds. This requires the integration and balancing of information which has already been internalized, on the

one hand, and, on the other hand, information which derives from perceptions of the external world, whether such information has been sought out or is volunteered. Inevitably, the individual's perceptual-cognitive construct of self and of others will, in turn, dictate his responses to self and others.

As might be expected, distortions in "perceptual-cognitive functioning are typically encountered in psychiatric patients. In many instances, these distortions may be attributed to two specific psychological phenomena. First, the individual may have developed an impairment in perceptual-cognitive functioning at an earlier stage of development, in the service of anxiety reduction and conflict resolution. Subsequently, this impairment is further complicated by motivational factors of equal urgency: the individual must regress to the use of primitive thought processes in order to diminish the acute anxiety arising from the current inadequacy of his integrative and adaptive capacities.

Therapeutic objectives. It is essential for such patients that the hospital minimize ambiguity, that every attempt be made to strengthen their confidence in the predictability of the behavior of others in the surrounding environment—and of the self as well. These goals can best be achieved by repeated enunciation, definition, and clarification of the patient's behavior in relation to others, and of the behavior of others in relation to the patient. The panic and acute anxiety which are associated with the psychotic episode, in particular, will then diminish. And at this point the patient, although still disturbed, can begin to make increasing use of the other resources the hospital has provided to alleviate his distress.

With particular reference to the acute psychotic reactions, it is unfortunately still too common that such acute behavioral disorganization is frequently treated in hospitals where the fragmentation of the helping relationship both through time and in the same situation is pronounced. Unlike other medical emergencies, the acute psychotic reactions are often treated perfunctorily and expectantly in receiving hospitals until the patient can be moved to a formal psychiatric hospital for definitive care. In the meantime, the patient is left to use his already learned and preferred behavior, now altered by regression and disorganization, not only to reduce the anxiety associated with his faltering adaptational struggle but also to master, mostly alone, the reactive panic of experiencing himself as psychotic.

The objectives of the organized milieu, as stated earlier with reference to long term psychiatric patients, are equally applicable to acute psychotic reactions. In brief, each member of the staff who comes into contact with the patient must attempt to minimize the ambiguity of the external reality which he represents directly as another self and symbolizes indirectly. Inevitably, each staff member will identify himself and specify his role for the edification of the

patient. The patient's impressions will derive from what the psychiatrist says and does to him, from what he is seen doing (and overheard saying) to other patients, and finally, from the role he has assumed, wittingly or unwittingly, in the total social context of the ward and hospital.

It is, therefore, essential that every psychiatrist on the staff be clear and confident about his own role action and about the role actions of his colleagues (including ancillary personnel). Otherwise, the anxiety, the resentment, the inter-role defensive maneuvers, and the ambiguity of action may severely diminish the ego-supporting benefits the patient may derive from his relationship to the ward personnel, however brief. Certainly, it is not necessary to underscore the therapeutic disadvantages of exposing the patient to many ill-defined, unspecified, and casual contacts (which by implication are rejecting) with various staff personnel who are either assigned to or just passing through the ward. To the patient who is already overwhelmed by a plethora of anxiety-induced, confusing information, such contacts can only impose an additional burden.

In any event, the goal of "conceptual closure," and the associated certainty of knowing cannot be achieved if the external situation is, in fact, unclear and ambiguous. By the same token, the patient sometimes asks persistently and provocatively for information about the hospital in relation to himself. These requests should also be responded to in the conscious modality of verbal communication, even if the psychiatrist also understands and responds to the patient's implicit need. This must be stressed, for under the aegis of trying to understand the patient's unconscious motivations, the hospital staff may fail to supply the direct, conscious anxiety-reducing answer and, instead, may "hedge" its responses to facilitate understanding of the unconscious significance of the patient's demand. There is a time to answer the patient directly; a time to draw certain inferences from his question and to answer him accordingly; and a time for interpretation. Those in the well organized therapeutic milieu can distinguish among them.

Similarly, it is obvious with respect to acute psychotic reactions, in particular, that when the ward personnel are prepared to answer questions clearly and authoritatively, and when orientation, dependency, assurance, self-esteem, and identity needs are adequately met by the milieu, bedlam is replaced by a well organized group of patients who, hopefully, will remain impaired only temporarily.

Structure and Organization of the Therapeutic Community

Physical plant. The geographical location and physical characteristics of the building which houses the psychiatric ward and its decor will also influence the effectiveness of the therapeutic milieu. Formerly,

the geographical placement of the hospital carried a possible connotation of isolation and rejection by the community; the size of the building and its age were correlated with massiveness, venerability, and chronicity; and the "accessories" which, ostensibly, were constructed to provide maximum security, suggested crime, rather than illness, and prisoner, rather than patient. Fortunately, within the past several years these physical characteristics have become the exception, rather than the rule. Thus, today, whenever feasible, the patient is returned to his local community for treatment, e.g., to the general hospital setting. Even the formal psychiatric hospital is becoming an open hospital to an increasing extent, and admissions are more frequently based on the voluntary decision of the patient, rather than legally coercive directives from others. Finally, in contrast to the earlier belief that the psychiatric hospital should be used as much as possible, psychiatrists now make every effort to limit the hospital stay of their patients. This, in turn, has changed the cue value of the psychiatric hospital, so that it is no longer equated with despair-engendering long term institutionalization, but with brief, helpful treatment.

Within the larger hospital complex, buildings which are specifically designated for the treatment of acute reactions, convalescent patients, or continued care cases, may have significant implications for the patient and, in fact, may further increase his psychological burden by adding impairing information about his inevitable fate as a patient, and the way he is perceived and valued by the hospital decision makers.

In contrast, the interior spatial design of the psychiatric hospital may or may not be congruous with the prevailing theories of behavior and of treatment. Certain principles should be borne in mind, however. For one, the goals of the therapeutic community seem to be achieved most effectively when patients can organize themselves into small groups which facilitate face-to-face interaction. Therefore, ward design should make it possible to form and maintain such groupings easily. Secondly, patients also need to be able to get away from the group at times, to retreat to some area where they can be securely and privately alone. The adequate fulfillment of this need requires a sensitive, flexible, secure therapeutic staff, as well as an arrangement of hospital space to ensure such privacy.

The interior "decor" of the hospital can also cue the patient as to the kind of behavior expected of him in specific hospital situations. For example, security hardware, crude furnishings, bare walls, seatless toilets, and open toilet stalls convey to the distressed and disordered patient that the hospital thinks it must protect itself against him. And that prophecy of further regression and loss of control may be fulfilled, in large measure, because of the increased anxiety, despair, and anger evoked in him

by this built-in hospital environment, and what it says to him.

Management of the therapeutic milieu. This reference to the self-fulfilling prophecy of the patient's behavior as a response to the physical environment of the hospital leads to consideration of the expectations which are communicated implicitly by the social environment and, more specifically, by the people who inhabit that environment, i.e., other patients as well as hospital personnel. Perhaps this is best illustrated by the frequently dramatic effects of a covert communication to the patient by a nurse or a psychiatrist of their bias about the prognostic implications of a diagnosis. The feeling of hope, or of hopelessness, which is thereby imparted is one of the most subtle, but most significant, aspects of the management of the therapeutic milieu.

The newly admitted patient must learn as rapidly and as effectively as he can how to be a successful patient in a particular hospital. To a great extent, the "culture" of the ward group will be conveyed to him by other patients. And every social group demonstrates an overt knowledge and communication of "the way we behave and do things here," and, by the same token, there is a covert and often conflicting system of the way things are actually done. The more inadequate the functioning of the hospital organization, the greater the difference between the overt and the covert systems among the staff as well as the patient group.

Daily meetings of all the members of the ward, patients and staff, to discuss and resolve the general problems involving human relations and administrative policy which stem from living in a collective society is the best insurance against too great a gap between the therapeutically desirable operation of the ward and its actual mode of operation.

In a very real sense, the newly admitted patient participates in an already functioning therapeutic community. Therefore, one must be concerned not only with the creation of a therapeutic social organization for the patient, but with the psychologically healthy and productive social organization of the staff responsible for the therapeutic community. The hospital's formal organizational chart sometimes provides a helpful index of potential areas of task deviance. This indication of potential deviance may be due to the fact that the individual's position and functions in the organizational structure have not been clearly defined, or because his position and functions reflect administratively determined stress and conflict. Invariably, the response of ward personnel to conflict which is precipitated by top level administrative policy or procedure will take the form of altered motivational states with the consequent employment of characteristic coping strategies by psychiatrists, social workers, nurses, and other personnel. And these individual psychodynamic reactions

to "the system" almost always influence, in some measure, the efficient performance of therapeutic tasks and role action in general. In the case of the psychiatric hospital, these adverse reactions may be particularly evident in the staff's formal (e.g., psychotherapeutic) and informal contact with patients in their care.

To illustrate, conflicting directives to a nurse in charge of a psychiatric ward from two or more different administrative sources may evoke her anxiety or anger, or more often a mixture of both emotions, which will then take the form of resentment. Unless this resentment is very superficial, it will affect her motivation and will be manifested in her task performance and overt behavior. Admittedly, such changes may be situationally specific and of brief duration. But if such episodes occur frequently, to the point where they have been incorporated, albeit unwittingly, into the structure of superior-subordinate relationships within the hospital, then more permanent and more generalized coping preferences may result. Most nonprofit organizations, but hospitals especially, provide an opportunity not only for the resourceful execution of responsibility, but for the enjoyment of irresponsibility as well. Consequently, chronic resentment may ultimately take the form of a dehumanized "don't care" attitude; or it may be manifested in the subtle sabotage of the organization's tasks and goals or, as happens so frequently, in a rejection (by resignation) of the specific conditions of work imposed by the organization.

Since the nursing staff has had, in many psychiatric hospitals, to assume much of the day and night responsibility for the hospital society, the nursing service has implicitly assumed administrative power commensurate with their responsibility. This has led to an understandable reliance on their own hierarchical organization within the hospital. In such a circumstance the doctor in charge of a ward unit in a larger hospital may be in frequent conflict not so much directly with his charge nurse as indirectly because of the positions of both of them in the administrative structure.

In summary, then, the social structure of an organization continually influences the motivational state of the staff responsible for its effective operation. If motivation is altered, action may be altered as well. Action involves transactions with other personnel and may influence the motivation of these personnel. Hence, organizational stress which affects one individual's position initially may be communicated subsequently, either directly or indirectly, to many others in the organization. Organizationally induced negative tensions may then combine to divert the "final common pathway" of the therapeutic transaction and effectively nullify the helping intent or, even worse, transform it so that the patient's recovery may actually be impeded.

Obviously, the status of the patient in the hospital

community is an important concern in the creation of a milieu which will provide comprehensive and resourceful psychiatric treatment. By definition, status is a loose measure of one's power in a social system, and in many organizations it is determined more specifically by one's ability to influence the operation of that organization. Since, at best, the patient is perceived as a buyer of services, and at worst, as a beggar of services, it takes some flexibility to understand that, whatever his socioeconomic classification, the patient comes to the hospital to work too. Furthermore, his participation (i.e., task performance) in the organization is, in fact, a prerequisite for his therapeutic progress. Clearly, then, he must be permitted to collaborate in the joint enterprise of organizing and implementing the treatment process.

Specific therapeutic techniques. More specifically, the therapeutic community delegates administrative responsibility to patients, in keeping with its stated goal of restoring previously acquired adaptive capacities and developing new ones as a concomitant of exposure to the structured hospital environment. This delegation of administration can take many forms and need not be confined to participation in the formal patient government of the ward. This procedure does have certain advantages, however. For one, the patient's administrative participation is visible and therefore easily observed. And this may be the best way to give patients total responsibility in administrative and human relations areas.

Whatever the form of participant involvement of patients in the decision-making activities of the hospital, the essential requirement is that such power delegation be honest and be binding on the hospital administration. The therapeutic community is no place for "preplanned" decision making or for administrative role playing by patients.

Not only should all of the therapeutic resources of the hospital be seen as being employed for the patient, but as much as possible, and with the increasing reduction of impairment, such resources should be employed by patients in the service of their own recovery and further growth in resourcefulness.

Occupational, recreational, and general activities and other opportunities for action in the hospital should arise as far as possible out of the self-determined and self-decided needs of patients and not be impressed upon them by the staff. It is quite clear now that the simulated work concept of occupational therapy actually damaged the work behavior of the patients who had learned outside the hospital to give a full day's work for a full day's pay. And in these days of short hospital stay, vocational rehabilitation and retraining outside the hospital is the more rational way to skill or reskill our patients vocationally.

Finally, if much of the human distress which psychiatry tries to alleviate is directly or indirectly the result of failures of successful and resourceful individuation, then we need to be directed in our

therapeutic tasks not only by conceptions of developmental biology and of developmental psychology. The modern meaning of the hospital milieu is that it is an application of developmental sociology.

36.2 DAY CARE: A PHASE OF PARTIAL HOSPITALIZATION

BERNARD M. KRAMER, PH.D.

Introduction

The development of day and night hospitals stems from two major concepts in psychiatry. First, workers have become increasingly aware that even seriously ill psychiatric patients do not necessarily require full time hospitalization. On the contrary, in the natural course of many, if not most, psychiatric disorders, the patient's need for constant supervision waxes and wanes. Furthermore, today, the prospects for recovery are viewed with vastly greater optimism than ever before. Thus, many patients who in the past would have been institutionalized for life are now thought to be eligible for day care or some other form of partial hospitalization at some point in the course of treatment.

Second, the concept of the mental hospital has been modified. It is no longer conceived of merely as an institution which offers "room and board" and custodial care. Rather, it is a force which is capable of exercising a positive influence through its therapeutic at-

mosphere, or, conversely, of exerting a negative influence because of unfavorable iatrogenic factors. Moreover, even under the most ideal conditions, hospitalization for protracted periods of time frequently tends to act against the patient's best interests, because it separates him from the community with which he must ultimately come to terms. Partial hospitalization, therefore, offers an alternative whereby the patient may reap the benefits of concentrated psychiatric care and at the same time maintain his ties with family and community.

Because of the essential validity of these basic premises, it is not surprising that day care has grown in popularity in the past several years. By the late 1950's, the number of day hospitals in operation in Great Britain and the United States had increased substantially. In this country, this growth has been reflected in federal regulations emanating from the Department of Health, Education, and Welfare, under the Community Mental Health Centers Act of 1963. In order to qualify for federal aid, a community mental health center must include in its program provision for partial hospitalization. As a result, at present, almost every state provides some kind of day care facilities for its mentally ill.

Day care is, in fact, now firmly established on a world-wide scale as a significant psychiatric facility. In the Soviet Union, as in the United States, the concept has been written into law. And in such countries as Nigeria, Yugoslavia, Greece, and Thailand, day care units are emerging to help solve problems arising from the shortage of trained psychiatric personnel and facilities.

History. The first modern psychiatric day hospital was organized by Dzhagarov in Moscow in 1933. In the West, the first major day hospital for severely ill psychiatric patients was established by D. Ewen Cameron in 1947 at the Allan Memorial Institute of Psychiatry in Montreal. The first such hospital in England was established by Bierer in 1948 at the Institute of Social Psychiatry. In the United States, day care units were created at the Yale Psychiatric Clinic in 1948, and at the Menninger Clinic a year later.

Organization of the Day Care Units

Although day care units may be organized in a variety of ways, three main patterns emerge.

Intramural facilities. The great majority of day care units are linked with a parent facility, such as a large state hospital or the psychiatric department of a general hospital.

Free standing units. These facilities, which are comparatively few in number, are independent of mental or general hospitals and operate as completely separate treatment centers.

Community facilities. Day care units may also be associated with mental health centers. These centers serve a variety of community needs and are being

established in increasing number as a result of the Federal Community Mental Health Centers Act.

Operational issues. Whatever its structure, certain issues are of universal concern in the operation of the day care unit, albeit to varying degrees. These include short term versus long term care; the degree of administrative control over admissions; staff initiative versus patient initiative; and, finally, the collaboration between the staff of the day care unit and the psychiatric in-patient service in the hospital with which it is affiliated (or the in-patient service of some other hospital in its health area, if it is an independent unit). The unit's approach to these issues will give shape to its program and determine its function in the community.

Short term versus long term care. Sooner or later, each unit must decide what balance it wishes to maintain regarding length of stay. Should it concentrate on providing intensive treatment for short stays, thus making its facilities available for larger numbers of patients? Should it respond to the long term needs of chronically ill patients? Or should it attend equally to both types of patients? The final decision will determine the type or types of patient admitted and the unit's treatment orientation.

Administrative control. The day care unit which exerts a measure of control over admissions, is, of course, in a better position to regulate the number and type of patient on its rolls. Without such control, there is the danger of an imbalance in the patient census and a concomitant threat to the unit's effectiveness. Pressures for admission are great. Nevertheless, each unit should be guided by one overriding criterion—acceptance of those patients who will best enable it to maintain its therapeutic atmosphere.

Staff initiative versus patient initiative. The therapeutic atmosphere will also be influenced by the attitude of the staff toward the patient. Each unit will decide whether it wishes to stress patient initiative, staff initiative, or a balance of both, in its policy concerning patient motivation. Should the staff take the initiative in motivating patients to improved levels of activity? Or should the staff adopt a permissive role and accept patient initiative as a governing factor? Those units which decide to stress patient initiative must take into consideration potential difficulties emanating from severely disturbed patients. On the other hand, staff initiative may be emphasized at the expense of therapeutic progress.

Collaboration with a psychiatric in-patient service. Finally, the day care unit must find an appropriate solution to the problem posed by those patients whose condition or behavior makes continued day care untenable. The most common solution is to arrange for the transfer of such patients to a psychiatric in-patient facility. Hospital admission may be expedited if the unit has a direct organizational tie with a state or general hospital or has established a formal or informal affiliation with such

an institution. In any event, a critical requirement for the successful operation of a day hospital is quick and easy access to an in-patient bed when the need for it arises.

Treatment Techniques

Specific and nonspecific therapies. Specific therapies may be executed in the day care setting as they would be on an in-patient service. In addition, however, the atmosphere and activities of the day hospital exert an independent therapeutic effect. Patients arrive in the morning, with or without a companion, and leave in the afternoon after a day of varied activities. Some work in the hospital; others engage in occupational or recreational therapy; still others, without specific assignments, interact with patients and staff. In some units, ward meetings serve as arenas within which patients may improve their interpersonal relationships. Whatever the particular schedule of activities may be, the primary task of the day care unit is to create a therapeutic milieu so that the environment itself may be of benefit to the patient.

Indications and Contraindications

Patients are frequently eligible for day care following a protracted period of full time hospitalization. In large state hospitals, in particular, day care is used as a means of facilitating transition from hospital to community and may even prevent a relapse when the patient's adjustment to the community appears in jeopardy. In addition, direct admission to a day hospital may preclude the need for full time hospitalization. Finally, the day hospital offers a significant potential solution to the shortage of mental health resources, which represents a national problem.

Experience indicates that day care appears to be suitable for patients in almost all diagnostic categories, and with illnesses of varying severity. Age, sex, and other background characteristics do not appear to be barriers to this form of treatment. Experience has also shown, however, that patients who are clearly suicidal and acting out patients may present serious difficulties in management. As a result, some units have excluded these patients. Certainly, administrators should be cautious about admitting such cases and make careful arrangements for their care and management.

Results of Treatment

Several attempts have been made to assess the effectiveness of day care. Nevertheless, no definitive evidence has been marshalled to date to prove that, for certain cases, partial hospitalization is more effective than full time hospitalization. The most valid conclusion would seem to be that day care is no less effective than traditional methods of patient care.

At the same time, however, the value to the patient of maintaining community and family ties would appear to offer a *prima facie* reason for suggesting that partial hospitalization, in general, and day care in particular, are vital elements in the armamentarium of comprehensive community-oriented psychiatry.

36.3 OCCUPATIONAL THERAPY

LEONARD A. WEINROTH, M.D.

History

Occupational therapy as "moral treatment."

When Pinel and those who followed him "took the chains off mental patients," it became apparent that this was only a first step in the more civilized, more humane, and more scientific treatment of the mentally ill. It pointed up the fact that psychiatric patients wanted and needed to have their time occupied; that, not unlike normal people, they too became restless when they had too much free time on their hands. Accordingly, various crafts programs were introduced into mental institutions, in the hope that they might have a curative effect upon the patients. In the United States such programs were part of what was then called "moral treatment," and they included walks, games, and religious services, in addition to crafts and farming.

It soon became apparent, however, that many patients were too negativistic and withdrawn to participate in such programs. In fact, frequently, depressed, phobic, and paranoid patients were even unable to leave the ward. In response to the need to involve these patients in such activities, occupational

therapy as an ancillary aid to psychiatric treatment began to emerge as a new profession. It received its greatest impetus, particularly in the United States and Canada, from World War I, when it became evident that occupational therapy was an essential part of the rehabilitation of men who sustained wartime injuries, whether physical or mental.

"Occupational therapy prescription." Art as an important medium of expression was added to the armamentarium of occupational therapy, in the form of painting, sculpture, and dancing. Reading and discussion groups were also formed. In general, an attempt was made to fit the task to the needs of the individual. This orientation was termed "occupational therapy prescription." More specifically, the psychiatrist was expected to be able to determine the particular type of activity best suited to a specific psychopathological phase or diagnostic category.

A classic example of this approach would be assigning a task which involved hammering to a depressed patient who could not externalize his aggression.

Current Techniques

"Free choice" approach. With the accumulation of clinical experience and the greater influence of psychoanalytic psychology within psychiatry, therapists moved away from the concept of specific "occupational therapy prescriptions," to the "free choice" approach. According to this approach, patients newly admitted to an institution are told about the available arts, crafts, and other occupational therapy facilities, such as kitchens and sewing machines, but they are not urged to use them, based on the premise that the majority of patients will participate in these activities sooner or later during their hospital stay. Such unstructured work situations are much more instructive to the therapist than were previous attempts to fit patients into a prescribed mold. When utilized in this manner, occupational therapy supplies data not unlike those elicited from projective tests.

Occupational therapy in the general hospital. On the basis of observations made in occupational therapy at Mount Sinai Hospital, Linn, Weinroth, and Shamah were able to distinguish four phases in the evolution of acute psychiatric illness in general hospital patients.

Phase I. Acute psychiatric patients are admitted to a general hospital because they are not able to function in the community. Some acute crisis in their lives has precipitated, or exacerbated, the illness. Upon admission, they are generally too confused, or too agitated and disturbed to be able to do anything at all in occupational therapy. However, after a varying period of time they quiet down sufficiently to become aware of their surroundings. It is at this point

that they are likely to begin to take advantage of occupational therapy facilities and recreational activities. During this initial phase they are likely to paint or sculpt all sorts of symbols and unstructured blotches of color which reflect their central fantasies.

Phase II. As their contact with reality increases, they enter the second phase of hospitalization. Concurrently, they begin to produce more conventional things, such as pocketbooks and ashtrays, and to paint more conventional canvasses.

Phase III. When the time comes for the patient to leave the hospital, his work becomes much less structured once again, as part of a predischARGE symptom flare-up. This third phase lasts for as long as it takes him to accept the idea of leaving the hospital.

Phase IV. The separation from the hospital and the therapist, i.e., the weaning reaction, constitutes the fourth phase. In the course of this phase the patient may want the occupational therapist and/or his psychotherapist to keep one or another item he produced during his hospital stay. If he leaves the hospital before he is quite ready to do so, he may leave behind a painting or a piece of sculpture. Then, at some future time, when he is better prepared to function independently, or if he forms another meaningful relationship in the interim, he may return for the article.

Long term implications. Patients should be encouraged to continue their interest in occupational therapy, to the extent that facilities permit, after discharge from the hospital. They may continue to visit the hospital, if this is possible, or engage in such activities in a community facility which is not affiliated with the hospital. Thus, occupational therapy can perform a liaison function between the patient and the hospital, on the one hand, and the patient and the community, on the other. Furthermore, occupational therapy activities may even help the patient develop a new interest or point to a new professional orientation.

Therapeutic Applications

Many psychiatrists make extensive use of occupational therapy and, in particular, of artistic productions, to gain greater insight into their patients' psychological functioning. Patients are encouraged to associate to, or explain their paintings or sculpture; the therapist then offers interpretations based on the content, form, or color of the artistic productions. Other therapists feel that utilizing certain color tensions will help patients to abandon more regressive states and strengthen the integrative functions of the ego.

It is often possible to learn how a patient feels about himself and others through the medium of occupational therapy. The distortions which character-

ized his primary object relationships are often reflected in his productions; and concomitantly, he is able to indicate his present feelings toward his family. Similarly, the hospitalized patient's attitude toward his fellow patients and the hospital staff are demonstrated in his art and in his other activities. Moreover, his feelings toward his therapist, i.e., transference and counter-transference phenomena, are often expressed in occupational therapy.

Not only conscious attitudes, but much that is unconscious is often bared in this manner. Ego and superego attitudes, both conscious and unconscious, are reflected in the occupational therapy productions. Thus, from a structural point of view, it is often possible to see what the predominant drive may be during a particular phase of the illness.

Chapter 37

Evaluation of Psychiatric Treatment

37.1 • • •

JEROME D. FRANK, M.D., Ph.D.

Clinical experience clearly indicates that some patients are helped considerably by psychiatric treatment. Information is sparse and inconclusive, however, as to the relative effectiveness of different types of therapy in different types of psychiatric illness. This section will present a brief review of the major issues involved, in an attempt to shed further light on this question.

For proper evaluation of a particular form of therapy, the changes it produces in a homogeneous sample of patients should be compared with those occurring in a control group which does not receive such treatment but is matched with the experimental sample in respect to all other relevant variables. Moreover, the treatment itself should be described in terms that will permit its replication. Finally, the criteria of improvement should be defined objectively.

The psychiatrist engaged in such an investigation will find it difficult to meet these conditions: psychiatric illness is the manifestation of a complex interplay between personal vulnerabilities and environmental stresses. Moreover, these stresses characteristically involve the individual's personal interpretation of his experience, rather than threats to his biological integrity which can be evaluated objectively. Psychiatric treatment introduces new, and presumably beneficial, variables into this system which interact with many other, less predictable variables. The specific effects of the psychotherapies at the psychological level, and of the organic therapies at the biological level, have not been clearly defined.

To illustrate, the effects of the organic therapies on hospitalized patients are easiest to evaluate, because the treatment agent can be defined quantitatively and the environment can be controlled. Nevertheless, even with these therapies, the interplay between organic and psychosocial factors must be taken into account. Thus, the subjective effects of lysergic acid

diethylamide (LSD) may be very different, depending on whether the psychological setting is supportive or threatening; and much of the initial beneficial effect of the phenothiazines may have been due to the increased optimism of the treatment staff.

The evaluation of out-patient psychotherapy presents the greatest difficulties, however. For one, the therapeutic agent is an interpersonal relationship which defies precise definition. Secondly, the patient is exposed to treatment for only a short period of his waking life. The patient's experiences between sessions may be more important in determining the outcome of treatment, and therapy may influence these in subtle and uncontrollable ways. For example, the knowledge that the patient is undergoing psychiatric treatment may lead other people in his environment to think of him as "sick" and affect their behavior toward him. If the patient's interpersonal behavior changes in the course of treatment, this will inevitably produce concomitant changes in the behavior of his family which may enhance or impede his future progress. Similarly, the patient's progress may be impeded when the illness has maintained the emotional equilibrium of a family, so that his improvement is perceived as a threat by the other members.

Space limitations preclude discussion of the statistical and experimental methods which are presently being used to evaluate specific therapeutic techniques. Two brief examples may be cited. The nature of the therapeutic relationship has been explored by means of correlational techniques, in studies of large numbers of different types of patients and their therapists. These studies revealed that patients who receive a high degree of warmth and empathy from their therapists tend to improve; on the other hand, when patients fail to perceive these qualities in their therapists, they tend to get worse. A study using the method of experimental manipulation found that, on the average, psychiatric out-patients who had been prepared for psychotherapy by a special "role induction interview" showed greater improvement after 4 months of treatment than did an unprepared control group.

Basic to all attempts to evaluate psychiatric treatment is the description of criteria of improvement.

The remainder of this section will consider some of the major issues surrounding this area of investigation.

Criteria of Improvement: General Issues

Intuitive versus operationally defined criteria.

It is plausible to maintain that success in achieving the goals of certain forms of psychotherapy (e.g., helping the patient achieve a more integrated personality, or greater self-realization) can never be determined objectively. We must recognize that, while such aims may often be appropriate, they may always elude operational definition. At the same time, however, we must either assume that at least some significant criteria of improvement can be reduced to operational terms or abandon the scientific study of psychiatric treatment. Fortunately, in fact, the goals of many forms of treatment are more circumscribed, and the extent to which they have been achieved in a given patient can be specified.

Over-all versus specific measures. Because psychiatric illness reflects complex, multiple disturbances, at various levels of adaptation, improvement is seldom unitary. A patient's subjective symptoms and his interpersonal behavior may vary independently, or there may even be an inverse relationship between the two. For example, a patient's headaches may occur less frequently when he begins to express his anger openly. He may recover from one symptom only to substitute another, and various aspects of his behavior may change to varying degrees. Furthermore, different forms of treatment focus on different aspects of personality functioning. The behavior therapies, for example, concentrate on the amelioration of specific behavior disorders, whereas the insight therapies try to correct certain distorted perceptions. Obviously, when the criteria of improvement are defined in more specific terms, it becomes easier to evaluate the effectiveness of treatment.

Nevertheless, considering our present state of ignorance, an estimate of the patient's over-all improvement cannot be dispensed with. Depending on the individual case, such an estimate permits the rater to assign appropriate weights, on an intuitive basis, to improvement in particular facets of the patient's behavior. Accordingly, the over-all rating, "much improved," might be based on the disappearance of headaches in one patient, on a second patient's improved relationship with his wife, and on some combination of both of these factors in a third.

The estimate of over-all improvement is also a criterion against which more specific criteria can be validated. If, for instance, a patient shows improvement in regard to a particular complaint or pattern of behavior but nevertheless rates himself as unimproved on the whole, this suggests that, in itself, this particular symptom or disturbance in behavior did not motivate his decision to seek treatment; that

is, he did not regard it as a target complaint, referred to below. Furthermore, even if the nature of the improvement remains unspecified, the finding that one form of therapeutic intervention leads to greater improvement than another may be an important lead. In the long run, however, although they may be of some value, ratings of the patient's over-all improvement cannot make a significant contribution to our knowledge, because the data on which they are based cannot be made explicit.

Face validity versus construct validity. All criteria of improvement ultimately reflect implicit value judgments of the patient, the people important to him, and the therapist. Certain of these values are so widely shared, however, that any measure of improvement into which they have been integrated will receive universal acceptance; they are said to have "face validity." These would include subjective comfort; the capacity to establish mutually rewarding relationships with other individuals within and outside the family; the ability to do one's job adequately and to derive some satisfaction from working; and the possession of certain social skills.

As mentioned earlier, in a broad sense, these measures are universally accepted as the central objectives of all psychiatric treatment. Nevertheless, to demonstrate that a particular form of therapy produces improvement in these areas would not lead us very far toward our goal. Such a demonstration would not facilitate our understanding of various treatment processes or the validity of the theories which underly these modalities. In other words, treatment techniques must be evaluated in terms of improvement measures derived from the specific theories on which therapy is based. More specifically, the congruence between the patient's actual and ideal self would be the crucial measure of improvement for the client-centered therapies; the psychoanalytically oriented therapies would be evaluated on the basis of the patient's awareness of his inner needs, conflicts, etc.; and improvement in specific behaviors would determine the effectiveness of the behavior therapies. These measures then, would be said to have "construct validity." Because such measures are so closely bound to the theories from which they derive, however, they do not permit comparison of therapies based on different views. (Obviously, it would make no sense to evaluate a behavior therapy in terms of congruence between the patient's concept of his actual and ideal self.)

Moreover, all measures with construct validity are justified implicitly by the fact that they are closely related to measures with face validity. There would be little point in trying to increase a patient's insight or self-congruence if such changes were not reflected in an improvement in his subjective comfort and interpersonal functioning. These measures will overlap, of course; nevertheless, the patient's im-

provement must be evaluated in terms of both types of criteria.

Issues of base line and improvement interval. The ideal criterion in the evaluation of the effectiveness of treatment would be a comparison of the patient's status at the end of therapy and his "normal" state or even his potentially "best" state. The only practical alternative for such a base line, however, is the patient's state at the moment he seeks treatment, since only then can be observed directly. On the other hand, most patients come for help when the interplay of environmental stress and internal vulnerability has reduced their well-being to an abnormally low state; in brief, they are either in the throes of an emotional crisis, or at the bottom of a physiological swing. It follows that such a group of patients will be more distressed and incapacitated when they come to psychotherapy than they were a few months before, or will be a few months later—regardless of the effects of psychotherapy. And, in many instances, the patient's acute symptoms would disappear without therapy, as the effects of the crisis wore off or he entered a more favorable phase in his physiological rhythm.

The presence of large numbers of such patients in a test of the efficacy of any given treatment technique would yield a spuriously high improvement rate. Conversely, in a controlled study, in which such patients were represented in the control as well as the experimental group, the high rate of recovery in the control group might obscure the effectiveness of treatment.

An important statistical pitfall in comparing test scores in the evaluation of patients before and after therapy is that the degree of change manifested may be a function of the height of the initial score—the law of initial values. Those patients who are judged to be "sickest" initially, on the basis of certain criteria, will tend to show the most improvement in time, no matter what is done, and this may be erroneously credited to the treatment. This relationship may not apply for all diagnostic criteria, but it does in so many instances that any evaluation of patient improvement based on the differences between initial and subsequent test scores must allow for such errors.

The choice of the proper time interval for evaluating improvement presents related problems. The widespread view that the purpose of psychotherapy is to promote personality growth, together with the traditional medical 5-year follow-up, have combined to foster the conception of long term improvement as the ultimate test of therapeutic efficacy. Before the advent of the phenothiazines, no form of psychiatric treatment could be shown to produce a higher 5-year improvement rate than any other. And the 5-year improvement rate for subjects who had received any kind of psychiatric treatment was no higher than the rate for those who had received no specific treatment

at all. Typically, the treated group of neurotics and schizophrenics improves more rapidly than the control group and maintains its improvement, but the controls catch up eventually.

Obviously, long term follow-up results are necessary for a deeper understanding of the course of treated and untreated mental illness. However, the results of short term treatment should not be discounted. The production of temporary relief is a worthwhile goal, even if it does not affect the likelihood of recurrence. The treatment of a depression, for example, may be life-saving, if it shortens an isolated attack and prevents suicide, even though the next episode has not been postponed.

In any event, since the passage of time, in itself, may have certain therapeutic effects, the intervals over which improvement is measured must be equated in comparing different forms of treatment.

Types of Measures and Raters

In this subsection, the three major classes of criteria—subjective, behavioral, and physiological—will be considered briefly.

Self-reports. In evaluating psychiatric treatment, the court of final appeal must be the patient himself. Only he knows how troubled he was when he applied for treatment, and whether or not treatment has brought relief. Unstructured self-reports, solicited by the therapist, are subject to important sources of error, however. For one, the patient may lack the insight and sensitivity required for a good self-observation. Secondly, even when he does possess these qualities, his judgments are apt to be affected by his fears, hopes, disappointments, and colored by his wish to impress his therapist favorably. Self-reports by patients with a severely distorted grasp of reality or a disturbed communication system may be valueless. Finally, each patient's criteria for improvement are idiosyncratic, just as no two patients are identical constitutionally or psychologically. Consequently, it becomes difficult to compare self-reports of different patients. The construction of rating scales of symptoms, mood, self-concepts, etc., which enable patients to describe their status in these areas in comparable terms represents a partial solution to this problem.

The Q-sort. This method, in which the subject is asked to arrange a large number of cards describing different psychiatric complaints, permits a wide variety of statistical analyses. More specifically, the subject arranges these cards on the basis of their personal applicability: those which are most applicable are placed at one end of the scale; those least applicable at the other; and the rest in between. The number of cards to be placed at each scale point is specified, so that they form a normal distribution. In other words, very few cards are placed at either ex-

treme of the scale, and their number increases as one moves toward the middle categories.

Symptom check lists. This is another type of self-report in common use which can be analyzed to yield mean distress scores, as well as scores based on categories of symptoms. In neurotics, for example, the degree of over-all distress seems to be determined primarily by the severity of symptoms related to anxiety and depression. Since these may change markedly in the course of a single interview (particularly if treatment provides for the adjunct use of psychopharmacological agents), mean distress scores are too labile to distinguish the relative effectiveness of different types of treatment.

Analysis of target complaints. These are defined either as symptoms which are mutually acknowledged by patient and therapist, or as the patient's presenting complaints which he cites as his reasons for seeking treatment. They are considerably more stable than mean distress scores over a short time span and therefore permit comparison of different forms of treatment. To date, the analysis of target complaints has proven particularly useful in the evaluation of drug therapies; however, many workers believe that they can perform a similar function in the evaluation of the psychotherapies. This belief gains support from an experiment showing that brief desensitization therapy more effectively relieves performance anxiety than insight therapy.

Despite these optimistic reports, inevitably, the analysis of target complaints presents certain methodological difficulties. While these are not so great as to negate the potential value of this procedure, they merit brief discussion. For various reasons, the patient's initial target complaints may change as therapy progresses. As he develops confidence in his therapist, the patient may reveal problems he had concealed at the outset. Again, the insight he gains in the course of treatment may lead him to reformulate his initial complaints, so that they no longer resemble the version in which they were originally presented. Finally, the comparison of one patient's complaints with another's presents obvious problems.

Minnesota Multiphasic Personality Inventory. The distorting effects of a patient's motivations on his self-report can be reduced by measures which are not obvious to the patient. This test solicits information on a large number of complaints, feelings, and behaviors. The significance of the individual patient's answers emerges after they have been compared statistically with the responses of other patients.

Semantic Differential test. This test has a similar goal and has become increasingly popular. The test consists of a set of scales, which consists of such ratings as sharp-dull, clean-dirty, etc. Through statistical analysis of the patient's scores, each concept can be assigned to a three-dimensional "meaning

space," whose axes are good-bad, strong-weak, and active-passive. Apart from its potential value as a tool to facilitate the evaluation of the over-all effects of treatment, this test shows considerable promise as a means of demonstrating changes in the patient during treatment in relation to specific concepts.

Projective tests. The Rorschach test and the Thematic Apperception test are most widely used. These tests are designed to facilitate the expression of fantasies and other aspects of the patient's psychic life, the significance of which is not apparent to the patient (and which, in fact, might not be accessible to the therapist otherwise). Unfortunately, although the validity of these tests as an index of the presence of pathology has been established, they have proved disappointing as criteria of improvement during treatment, probably because the qualities of personality functioning they elicit are not easily modified.

Ratings of behavior. While, theoretically, behavioral ratings may be assigned to out-patients as well as in-patients, behavior observations are particularly applicable to in-patients for obvious reasons. Moreover, since, by definition, the behavior of hospitalized patients is so disturbed that they cannot function outside the institution, even crude measures of behavioral change are useful. Typically, this procedure involves the observation (and rating) of the patient's behavior at regular time intervals around the clock, and a subsequent check of the reliability of these observations by a comparison of the ratings made by various members of the treatment staff.

As mentioned above, ratings of behavioral change in this patient population are typically based on crude indices, which, however, may have complex determinants. To illustrate, while discharge from the hospital would logically be considered an indication of significant improvement in the patient's behavior, in fact, it is far from a simple function of clinical progress. The decision to discharge the patient may be strongly influenced by hospital policies, the availability of facilities for the patient's care in the community, and the attitudes of those to whom he will return.

With regard to out-patients, except for home visits which are made rarely (albeit for understandable reasons), ratings of changes in the patient's behavior which occur outside the therapeutic hour must be based on the patient's or relatives' reports, with all the sources of error this implies. A possible solution to this problem may lie in the microscopic analyses of specific aspects of the patient's behavior such as his patterns of interaction with the therapist, and structural characteristics of his speech, during the therapeutic session. These aspects of the patient's behavior may ultimately prove to be the most valid criteria of the patient's therapeutic course.

Physiological indices. Measures of autonomic activity have been used widely as indices of psychic stress, and therefore they would appear to have con-

siderable potential value for the objective evaluation of the effectiveness of improvement. These physiological symptoms which are considered to be psychologically determined include changes in heart rate, skin resistance, skin temperature, etc., as well as changes in the blood and urine levels of catecholamines, steroids, and other metabolic products. For example, clinical estimates of severity of depression correlate closely with urinary levels of 17-hydroxycorticosteroids.

Future Trends

Clearly, autonomic measures have the advantage of objectivity and scientific precision, and they have thrown increasing light on the role played by physiological processes in the etiology of mental illness. Their determinants have proved to be exceedingly complex, however, and the interpretation of findings presents corresponding difficulties. Recent improvements in instrumentation and methods of statistical analysis have brought a rapid surge forward, but the relationship of physiological measures to more direct indices of improvement as a result of psychiatric treatment still requires considerable clarification.

Despite the growing amount of reliable information concerning the effects of psychiatric treatment, much ignorance and uncertainty remain. It is helpful, under the circumstances, to remember that a lack of evidence to support the validity of a given proposition need not be interpreted as conclusive proof that it is false. More precisely, the past inability of psychiatrists to demonstrate differences in the effectiveness of various forms of psychiatric treatment does not prove that such differences do not exist. It merely points to the need for further research. With increasing sophistication in methods of defining and measuring criteria of improvement, and improved methods

of data analysis, rapid progress in this difficult field is occurring.

CHILD PSYCHIATRY

Two aspects of child psychiatry are especially relevant for readers of this textbook. The first of these concerns the status of child psychiatry within the broader framework of psychiatry in general. As a subspecialty which addresses itself to the developmental and behavioral problems of children, clearly child psychiatry has an important substantive role in psychiatry, and, in fact, childhood experiences have long been considered of crucial significance in the genesis of adult psychopathology. Yet, only recently has this subspecialty emerged as a field worthy of independent study and investigation. Some of the factors which may explain this lag are discussed by Kanner in his account of the history of child psychiatry.

The second aspect of child psychiatry which is of particular interest to readers of this volume concerns the problems of training. Until very recently theoretical concepts regarding the development and behavior of children derived from clinical data on adult psychopathology, rather than from the direct, intensive observation of children. Psychiatrists have just begun to realize that they must understand normal as well as atypical reactions in childhood, if they are to comprehend fully the pathogenesis of adult deviations. Concomitantly, there has been an increasing awareness of the importance of training in child psychiatry for all students of medicine and for all trainees in psychiatry, whatever their particular area of interest. Thus the study of child psychiatry is not the exclusive province of the specialist, but part of a sound education in general medicine, neurology, and the behavioral sciences, including psychiatry.

Because awareness of the criteria of "healthy" development is a *sine qua non* of child psychiatry, a section on normal child development precedes consideration of psychiatric evaluation, clinical descriptions,

and treatment. Thereafter, in keeping with the eclectic approach of this text, this area on child psychiatry addresses itself to the three basic levels of organization in the child—the psychological, the social or interpersonal, and the physiological. In childhood, more than at any other stage of development, all three levels mesh and intertwine. Of equal importance in the consideration of childhood is the awareness of the constant change which is taking place within the matrix of the child's relationship to his family and society: both the child and his external world are in a continual state of flux. It follows, then, that the psychiatric evaluation of the child will include an assessment of his total functioning, including his level of physical and psychological development, in any given situation, as well as the degree to which his functioning reflects the impact of his environment.

The fact that certain variables are idiosyncratic of childhood has particular significance for the classification of behavioral disorders in childhood. It has long been recognized, in this connection, that the classification of psychiatric disorders in childhood and adolescence, as provided in the *Standard Nomenclature of Diseases and Operations* of the American Medical Association (which is identical with the *Diagnostic and Statistical Manual: Mental Disorders* of the American Psychiatric Association) is unsatisfactory. This was officially noted by the Committee on Child Psychiatry of the Group for the Advancement of Psychiatry (GAP) (Report No. 62, Vol. 6). The Committee pointed out that the *Standard Nomenclature* "leaves untouched many of the developmental gradients of psychopathology in childhood and adolescence. The need remains for a separate classification dealing with childhood and adolescence . . . despite some overlap between the problems of the latter age group and

those of adults." Accordingly, the GAP proposed a new classification of psychopathological disorders in childhood as of 1966.

This classification is based upon three basic propositions which form a theoretical framework. These include: (1) the psychosomatic concept of the unity of mind and body, and the interrelatedness of psychological and somatic processes; (2) the developmental dimension central to the study of the child; and (3) the psychosocial aspects of the child's existence in the family and society. These propositions support the concept of multiple etiological factors, of a predisposing, contributory, precipitating, and perpetuating nature, which are involved in disease states. Portions of the GAP monograph are summarized below; other passages are summarized in various sections throughout this area. However, in view of the importance of this contribution, the reader is urged to refer to the detailed presentation provided in the original report.

The GAP classification, while utilizing many of the nosological definitions included in the *Standard Nomenclature*, has introduced the concepts listed below for the first time in any major classification system:

1. The category "healthy responses" permits "the identification of healthy patterns of response" and reduces "the traditional tendency to magnify minor problems and fit the child into a pathological category or diagnose the absence of disease." This category emphasizes "the need for the assessment of positive strengths in the child wherever possible and [avoids] so far as possible the diagnosis of healthy states by the exclusion of pathology." Criteria covering intellectual, social, emotional, personal, and adaptive functioning, as well as stage-appropriate psychosocial functioning, are given. Included in this category are developmental crises (such as the "identity crisis" in adolescence) and transient situational crises (as, for example, the "work of mourning" in the healthy grief reaction).

2. "Developmental deviations pertain to overall deviations in maturational rate or sequence or to different aspects of personality development." This category "delineates those deviations in personality development which may be considered beyond the range of normal variation in that they occur at a time, in a sequence, or in a degree not expected for a given age level or stage of development." These may include deviations in maturational patterns or in specific areas

of development, such as motor, sensory, speech, cognition, social, psychosexual, affective, or integrative development. Such deviations may either be resolved with the passage of time or lead to a more structured disorder. Healthy responses and developmental deviations in infancy and childhood and in adolescence are discussed by Chess and Hornick, respectively, in this text.

3. Another innovation in the GAP classification is the detailed "Symptom List," specifically applicable to children. The GAP list is similar to the symptom list designed primarily for adults which is included in the *Standard Nomenclature*.

4. "Reactive disorder" replaces the term "transient situational personality disorder," in the GAP report. Examples would be the reactions to hospitalization and illness discussed by Prugh in Section 40.3, below.

5. The "Special symptom reactions" in the *Standard Nomenclature*, such as learning, speech disturbances, and enuresis, are included in the GAP "Symptom List" to be used under different nosological headings in relation to a primary clinical diagnosis. To quote from the GAP report:

Thus, enuresis may be shown as an age-appropriate phenomenon in a young pre-school child, under the heading, *healthy response*; as a symptom of a regressive nature in a *reactive disorder*; as a continuing feature of a *developmental deviation*; as part of a neurotic picture involving *conversion mechanisms*; or as one symptom in a *chronic personality disorder* or a *psychosis*. . . Only in this way can data be organized systematically in relation to the evolution and shifting of symptom patterns or part reactions and their associations with differing personality pictures.

The GAP report classification includes, as does the *Standard Nomenclature*, psychoneurotic personality, psychotic, psychophysiological (psychosomatic) and brain disorders, and mental retardation.

The editors have retained the *Standard Nomenclature* where applicable in this textbook and utilized as supplementary data some of the newer headings included in the GAP report, which are omitted in the *Standard Nomenclature*. They recognize that the *Standard Nomenclature* in general, and particularly as it pertains to child psychiatry, is in need of revision. The GAP classification is presented as a possible alternate model which, while not official or time-tested, is worthy of consideration.

Chapter 38

Introduction to Child Psychiatry

38.1 HISTORY OF CHILD PSYCHIATRY

LEO KANNER, M.D.

The concept of child psychiatry as a distinct specialty did not arise—and could not have arisen—before the 20th century. The story until then is not a narrative of a practiced discipline but rather an account of the building stones that eventually formed the foundations of the present day structure. The time is not too far in the past when children were a part of the household chattel, when Dickens' *Oliver Twist* was fiction based on stark reality, when unrestricted child labor sucked health and spirit out of impecunious youngsters, when the Prussian police denounced the first kindergartens as hotbeds of socialism.

Eighteenth Century

There is no evidence of any organized concern with child development and child behavior in antiquity or in the Middle Ages. It was not until the era immediately preceding the French and American revolutions that the new gospel of the rights of man had in its wake a spurt of reforms extended to the hitherto neglected or oppressed. Shackles began to be removed from psychotic persons. Voices were raised *against* slave trade and *for* humane treatment of prison inmates. Handicapped children became the recipients of constructive attention. Pereire proved that it was possible to teach deaf-mutes to communicate with those around them. In 1784, Haüy founded in Paris the first school for the education of the blind.

Nineteenth Century

Itard, while trying to civilize the "savage boy of Aveyron," introduced methods designed to help severely retarded children. In 1841, Guggenbühl opened, on the Abendberg in Switzerland, the first residential center for young mental defectives. This was so startling an innovation that princes, physicians, and clergymen came to admire and to learn. Within a

short time, similar institutions were set up in several European countries and, as a result of the efforts of Samuel Gridley Howe, have been set up in this country as well since 1848.

Meanwhile, inspired especially by Rousseau's *Emile*, published in 1762, and the writings of Locke, a few scientists became curious about the stages of infantile development. They observed their own offspring and recorded the day-by-day unfolding of their functions. They followed the example of the Swiss educator Pestalozzi, whose diary of his son, however, still carried a ballast of mysticism and pious idealism. Darwin, Preyer, and others were subsequently able to strip their observations of unwarranted generalizations. In the 1880's, Stanley Hall analyzed the responses obtained from questionnaires sent out to thousands of parents and presented data in terms of percentage calculations. A new body of research emerged that, as developmental psychology, made up in the span of one generation for much that had been neglected throughout the ages.

Sporadic contributions to the knowledge of children's deviant behavior began to come from the fields of neurology, pediatrics, and psychiatry. These interests existed alongside each other, with only tenuously maintained areas of mutual contact. Toward the end of the 19th century, several texts were published on "psychic disorders," "mental diseases," or "insanity" of children. Behavioral deviations interested Emminghaus, Moreau de Tours, Ireland, and Manheimer, chiefly as they seemed to fit diagnoses according to classifications devised for adults. These treatises represented a first step toward the unified consideration of early life neuroses and psychoses. But, on the whole, psychiatrists still kept themselves aloof—children were neither heard nor seen by most of them professionally.

Twentieth Century

First decade. In 1900, the Swedish sociologist Key, having waged a successful battle for the emancipation of women, predicted that the 20th century was destined to be "the century of the child." A number of things happened that tended to confirm her prophecy.

In 1899, Illinois and Colorado had passed statutes establishing juvenile courts, in which delinquent chil-

dren were to be handled separately and differently from adult violators of the law. As juvenile courts began to spring up all over the country, some of the judges, eager to learn *why* the young offenders had been driven to their transgressions, consulted psychiatrists, who thus were obliged to occupy themselves with children's behavior and its motivations. As a result, Healy founded the Juvenile Psychopathic Institute in 1909 in connection with the Chicago Juvenile Court and published his book, *The Individual Delinquent*, in 1915, a report based on case studies instead of diffuse speculations on delinquency in the abstract.

In 1905, Binet and Simon made public their intelligence scale, introduced by Goddard in this country in 1910 and adapted in 1916 by Terman to its geographic and ethnic area. These tests afforded a concrete means of helping teachers evaluate a child's ability to grasp classroom instruction. This was the first reliable attempt to prevent educational mismanagement.

Simultaneously, adult psychiatry underwent major changes. Kraepelin's work served as a stepping stone toward the humanization of the specialty. His clear descriptions of symptoms, the *what* of mental illness, aroused curiosity about the *whence* and *why*. Freud and Meyer advocated a dynamic attitude that saw the origins of present trouble in experiences of the past. Biographic exploration became an obligatory part of history taking. Biography, if pursued consistently, leads always back to the time when each patient was a child. This search for the meaning of childhood events as precursors of later illness created an appetite for immediate acquaintance with troubled children themselves and ripened the thought of prophylactic intervention at the time of the earliest onset. This thought was taken up vigorously by Beers, who in 1909 founded the National Committee for Mental Hygiene.

Thus, between 1899 and 1909, the decks were cleared for individual work with problem children. Juvenile courts, psychometry, dynamic psychiatry, and the mental hygiene movement served as the main incentives. Educators, psychologists, and psychiatrists began to *think about* children in a practical, individually helpful manner. Previous indifference and supercilious disdain were replaced by an attitude of sympathy and a desire to understand and to be of service.

Second decade. The following decade was mainly one of legislative implementation of some of these insights, a transition from unorganized philanthropy to systematic communal endeavor. The emphasis lay on environmental cushioning of the decidedly delinquent, the noticeably retarded, and the woefully neglected. Probation officers were added to the juvenile courts. Foster home organizations were authorized to remove children from homes in which they suffered from proved parental mistreatment. Special classes in public schools helped retarded and otherwise handicapped

students to get an education commensurate with their abilities. The principal goal was protection from brutality, bad examples, malnutrition, gangdom, and scholastic competition against overwhelming odds. People no longer merely *thought about* children but were prepared to *do something to* them with the aid of adequate community facilities.

Third decade. In 1921, Thom opened the Boston Habit Clinic for the guidance of problem children; in 1922, child guidance clinics were set up in a few communities; in 1930, there were about 500 such clinics, and more than 50 countries sent delegates to the First International Congress of Mental Hygiene in Washington, D. C. These clinics were tridisciplinary teams of psychiatrists, psychologists, and social workers. They added a new dimension to the study of personality development. Until then, most theories had centered around innate, constitutional, instinctive propensities of the individual. The clinics broadened the scope beyond what was going on within a child to include the external, attitudinal forces that impinge on him. This was a departure of major importance, which saw emerging behavior as the consequence of a fusion of centrifugal and centripetal influences. Treatment therefore embraced efforts to do something *for* children by working constructively with the family and the school. The mutuality of parent-child relationship became a new topic of investigation.

In 1926, Homburger published his book on the psychopathology of childhood. This was a pioneering enterprise encompassing all that was then known about the subject and carrying together all the building stones to make them available for an integrated edifice. Anna Freud began to apply psychoanalytic principles to the treatment of disturbed children and, through the introduction of play therapy, formulated a method for including the child patient himself in the remedial arrangement by doing things *with* him as well as *to* and *for* him.

More recent events. In 1930, a children's psychiatric service was inaugurated at the pediatric department of The Johns Hopkins Hospital. Thus, it became possible to reach children, from the beginning of life to and beyond pubescence, with any kind of developmental and behavioral anomaly, with any kind of single and combined organic, intellectual, psychogenic, attitudinal, and sociological implication. The different clusters of building stones found themselves in one place and could be assembled under one roof.

On May 19, 1933, at a meeting of the Swiss Psychiatric Association, Tramer suggested for this new branch of medicine the name *Kinderpsychiatrie*, to which he gave added currency in the title of the first journal of the specialty founded by him in 1934. In 1935, Kanner used the equivalent term "child psychiatry" in the first textbook of the discipline in the English language. In 1937, at the initiative of Heuyer, a congress met in Paris under the heading of *psychiatrie infantile*. Child psychiatry acquired an acknowl-

edged identity, a name of its own, and a vigorous representation.

This recognition has led in the last 3 decades to the establishment of training centers and professorships in leading universities, specialized periodicals, national and international societies and conventions, the creation of out-patient clinics and residential units for emotionally disturbed children, and intensive research activities.

In the 1930's and 1940's, fundamental contributions were made to the study of childhood psychoses by Lutz in Switzerland, Ssuharewa in Russia, Creak in England, and Despert, Bender, Kanner (infantile autism), and Mahler (symbiotic psychosis) in this country. Goldfarb's work triggered interest in the effects of early maternal deprivation. Levy and Allen gave new directions to psychotherapeutic endeavor. A field of primary prevention has begun to include epidemiology and prenatal and paranatal factors in the scope of child psychiatry.

Child psychiatry has come of age and is here to stay. It has its roots in many areas: education, pediatrics, neurology, general psychiatry, psychology, sociology, jurisprudence, genetics, and biochemistry. It has been able to integrate all these considerations into one unified though widely ramified discipline within a short time.

38.2 NORMAL CHILD DEVELOPMENT

LEON EISENBERG, M.D.

This section attempts to define the concept of development and to indicate its implications for the understanding of human personality. Personality is

used here to mean a set of attitudes and action tendencies—probabilities for given patterns of overt behavior in specified social fields—that characterize an individual at a particular period; it includes both affective and cognitive elements. Personality is viewed as an emergent from the interaction between individual physiological traits, personal experiential history, and social field forces. The apparent constancies of personality in an individual are commonly taken to indicate a crystallized set of mental structures that it is difficult to alter once maturity has been reached; this view pays insufficient attention to the consequences of uniformity of social role in serving to maintain the manifest regularities of behavior.

Although this discussion concludes at the stage of adolescence, developmental changes continue through senescence; personality is constantly in the making.

History of Developmental Concepts

If a historic perspective requires justification, Needham reminds us:

The history of science is the guarantee of its freedom. The mistakes of our predecessors remind us that we may be mistaken; their wisdom prevents us from assuming that wisdom was born with us; and by studying the processes of their thought, we may hope to have a better understanding, and hence a better organization, of our own.

Forces behind development

Preformationist concept. A fragment surviving from the Ionian philosopher Anaxagoras, who lived in the 5th century B.C., comments on the origin of things: "Hair cannot come out of not-hair, nor flesh out of not-flesh." This notion is echoed in the Hippocratic writings on embryology:

Everything in the embryo is formed simultaneously. All the limbs separate themselves at the same time and so grow, none comes before or after the other, but those which are naturally bigger appear before the smaller, without being formed earlier.

This quotation is of particular interest because of its appeal to reason rather than experience. Other passages make it clear that embryos had been examined. The observed was explained by a preformationist doctrine that coerced and restricted the observations that at face value would have suggested unequal times of beginnings for the different parts of the embryo. This doctrine was given poetic expression by Seneca:

In the seed are enclosed all the parts of the body of the man that shall be formed. The infant that is borne in his mother's womb bath the routes of the beard and hair that he shall wear one day. In this little masse likewise are all the lineaments of the body and all that which posterity shall discover in him.

For all the naivete—by present day standards—embodied in these quotations, they are no mere exercise in antiquarianism. The same notions implicit in classic genetic theory are still adhered to, in modified form, by many biological and behavioral scientists.

Epigenetic concept. An alternate theoretical conception was first formulated by Aristotle in the 4th century B.C. The ovum being unknown and not to be discovered for another 2 millennia, he concluded that the semen, as the active shaping force or soul, acted on the catamenia (menstrual fluid) as the base material to form the fetus. Aristotle grappled with the perplexing question of the order of formation of the parts. Having opened eggs at various stages in development, he commented:

All the parts, as heart, lung, liver, eye and all the rest, come into being either together or in succession. . . . That the former is not the fact is plain even to the senses, for some of the parts are clearly visible as already existing in the embryo while others are not. That it is not because of their being too small that they are not visible is clear for the lung is of greater size than the heart and yet appears later than the heart in the original development.

In trying to account for the coming into being of that which was not evident at an earlier stage, he advanced an idea alternative to the preformationist view that the earlier stage was already present but simply invisible.

For if in a certain sense [the parts cannot be made by what is external to the semen], yet in another sense they can. It is possible, then, that A should move B and B should move C, that, in fact, the case should be the same as with the automatic machines shown as curiosities. For the parts of such machines while at rest have a sort of potentiality of motion in them, and when any external force puts the first of them into motion immediately the next is moved in actuality. As, then, in these automatic machines the external force moves the parts in a certain sense (not by touching any part at the moment but by having touched one previously), in like manner also that from which the semen comes, or in other words that which made the semen, sets up the movement in the embryo and makes the parts of it by having touched first something though not continuing to touch it. In a way it is innate motion that does this, as the act of building builds a house. Plainly, then, while there is something which makes the parts, this does not exist as a definite object, nor does it exist in the semen at the first as a complete part.

Aristotle's analogy of the automatic machine in which A moves B and B in turn moves C constitutes the first statement of the doctrine of epigenesis: successive differentiations in the course of embryogenesis. This is the essence of modern developmental theory.

Predeterminist concept. Preformationism, nonetheless, continued to be the prevailing doctrine, so much so that with the invention of the microscope the early microscopists described a homunculus with all the features of a man in the head of the sperm. Certain difficulties, however, troubled those of a theoretical bent. Hartsoeker, assuming divine creation to have occurred 6,000 years earlier and calculating the number of generations of rabbits during that interval, came to the conclusion that $10^{100,000}$ rabbits would have had to have existed in the first rabbit. Bonnet replied to this calculation with the rejoinder that it was always possible by adding zeros to crush the imagination under the weight of numbers. Bonnet

hailed preformationism as a victory of understanding over the senses.

However, the accumulating force of new data necessitated the abandonment of preformationism in its original form. With the development of better microscopes, the expected structures were not seen in early embryonic stages. Observation of the regeneration of limbs in adult organisms and the formation of embryonic monsters made the earlier position untenable. For preformationism, there was now substituted the doctrine of predeterminism. Stemming from the theological doctrine of predestination, it offered biologists a convenient fusion of science and religion. Swammerdam commented, "Thus original sin is explained, for all men were contained in the organs of Adam and Eve."

Predeterminism became the prevailing biological theory. It was implicit in Haeckel's aphorism: ontogeny recapitulates phylogeny, a slogan still quoted in current textbooks of biology. This notion was transplanted into psychology by writers as divergent as Jung and Gesell. Jung wrote: "Ontogenesis corresponds in psychology to phylogenesis. Consequently, . . . the state of infantile thinking in the child's psychic life, as well as in dreams, is nothing but a reecho of the prehistoric and the ancient." Gesell stated: "Infancy is the period in which the individual realizes his racial inheritance. This inheritance is the end product of evolutionary processes which trace back to an extremely remote antiquity." This concept of a set of psychic forces evolved in time long past but persisting as active and *unmodifiable* in the present is implicit in Freud's concept of the unconscious. He pointed out that the very emphasis of the commandment, "Thou shalt not kill," demonstrates that men are descended from an endless chain of "murderers" with a love of murder in their blood. He held that, since our attitude toward death is similar to that of "primitive" man, primitive man lives on in our unconscious and the primitive psyche is thus indestructible.

Scientific developments in embryology and in genetics called the predeterminist position into question. Direct intervention in embryogenesis led to the concept of the embryonic organizer or inducing substance—that is, a product of one group of cells that influences a contiguous or remote group of cells—an idea that bears a remarkable formal similarity to Aristotle's B, which, when produced by A, causes C. In genetics, Johannsen distinguished the phenotype from the genotype, the phenotype resulting from genotypic processes modified by environmental interaction in a sequential fashion. Just as the inducer is effective only within certain time limits, given environmental contingencies lead to specific consequences only when stage-related. The conflict between predeterministic and epigenetic viewpoints is still alive in embryology as well as in psychology, in instinct theory, ethology, and theories of intelligence.

Process of development. There are two contrasting models: continuous and discontinuous. The continuous view is concerned with a linear accession of events, the prototype of which is simple growth—that is, increase in the number and the size of cells. In a sense, this viewpoint is represented in psychology by associationist or stimulus-response theories in which sequential chaining of behavior is the essential principle and the learning of complex behavior is reducible to the forming of connections.

In a discontinuous model, the central assumption is a segmentation into stages or levels of development. What characterizes a stage or level is an internal structure or set of laws or, to use computer language, a stage-specific program governing the response of the organism to a given stimulus configuration. Lehrman's studies of the ring dove provide elegant illustrations of the differential effects of external stimuli at different stages of the reproductive cycle. A female ring dove, prior to courting by a male, ignores eggs and nests if they are placed in her cage; after courting, she broods if they are made available. Courting, to be effective, must occur after sexual maturity. Courting leads to nest building if materials are available; nest building activity itself increases the likelihood of subsequent brooding. The reproductive cycle does not occur in the absence of a mate and is abortive if nesting materials are not available or if the eggs are removed once they are laid.

It is appropriate to distinguish between *growth*, increase in the number and size of cells; *experience*, summation of all previous internal and external stimulation; and *maturation*, altered function resulting from interaction between growth and experience. Maturation, according to the viewpoint adopted here, is not linear but discontinuous, one might almost say quantized. Stages of development follow an age sequence, but stages and ages are not equivalent terms, though they are often incorrectly used as synonyms. The sequence of stages is not automatic but dependent on both central nervous system growth and life experience; chronological change can proceed while psychological maturation lags. There is some evidence that particularly favorable environmental stimulation can accelerate progression from one stage to another, and there is clear evidence that unfavorable environments can markedly delay some aspects of development.

There appear to be lower limits of age for the appearance of each stage, limits determined by central nervous system maturation; thus, no amount of verbal stimulation will lead to speech within the 1st half year of life. On the other hand, verbal stimulation during this period does play an important role in preparing the ground for the later acquisition of language. What is not known is whether there are upper time bounds for the acquisition of a given cognitive stage—that is, are there critical periods for the development of certain abilities, such that, if the appropriate

stimulus conditions are not provided within a given interval, the ability will never appear? Despite the common assumption that this is true, compelling evidence has not yet been provided in human development. It is more useful to assume that recoverability is possible, at least until thorough and exhaustive efforts at rehabilitation fail to bring results.

Development of the Human Species

Fossil evidence. For all his pride of place, man is a relative newcomer to the earth. If life on earth dates back some 2,000 million years, the life span of modern man has occupied less than one hundredth of 1 per cent of that total. In orders of magnitude, Primates have been in existence for some 60 million years. Hominidae for 1 million years, and *Homo sapiens sapiens* (modern man) for some 50,000.

The Cercopithecoidea (the catarrhine or Old World monkeys) and the Hominoidea superfamilies diverged from common ancestral forms. Of the Hominoidea—Proconsul, Dryopithecus, Sivapithecus, Oreopithecus, and Ramapithecus—the last appears as the most likely candidate for the form on the path to the Hominidae and the first to the Pongidae (the anthropoid apes). The family Hominidae, which includes both apelike men and man, has, as its oldest identified fossil precursors, the australopithecines discovered by Dart in South Africa. These animals possessed a brain case of 435 to 600 cc.—the same magnitude as that of the great apes, which ranged from 275 to 750 cc.—but a pelvis much like that of man; they have been found in association with pebble tools. It is still argued by some that the tools may have been made by a more advanced species preying on this more primitive precursor. Whether or not the fossil with a cranial capacity of 640 to 725 cc. and given the species name *Homo habilis* is to be differentiated from other australopithecines (*Australopithecus boisei*, *Austra-*

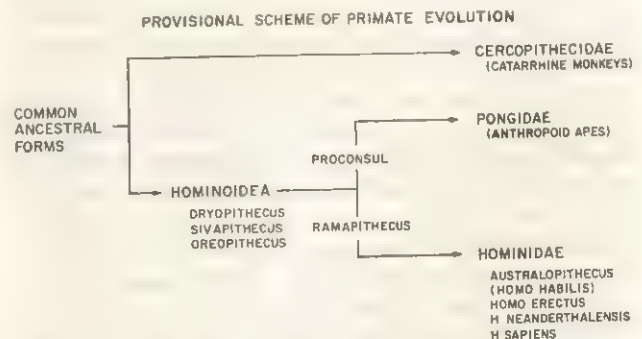

FIGURE 1. An outline, based on contemporary anthropological evidence, of the probable evolutionary pathways en route to man. Proconsul appears to be the ancestral prototype for the pongids and Ramapithecus for the hominids. Australopithecus is the earliest form identifiable as hominid and has been estimated, in the most recent finds (1967), to be two million years old. The sequence, while probably correct in general, undoubtedly is incomplete and subject to modification on the basis of future study and discovery.

lopithecus robustus, *Australopithecus africanus*), these Hominidae were either derivatives of the form or forms directly ancestral to *Homo erectus* on the line to man. *Homo erectus*, represented by *Pithecanthropus* and *Sinanthropus* with brain cases in the range of 775 to 900 cc. and 915 to 1,225 cc., respectively, are immediate or collateral fossil remains of the next step in the evolutionary radiation. Intermediate between *Homo erectus* and *Homo sapiens sapiens* is *Homo sapiens neanderthalensis* with a brain case, at least in some specimens, fully as large as that of modern man. Neanderthal man is generally thought to represent an offshoot that became extinct, perhaps destroyed by Cro-Magnon man in internecine warfare. (See Figure 1.)

This ordering is at best approximate and subject to modification by subsequent study and by the discovery of new fossils. Moreover, differences in definition of the characteristics for species differentiation and for the category of man continue to produce dispute among anthropologists. Distinctions cannot be based on single traits but must take into account the complex or pattern of traits, as Clark emphasized. Whatever the argument as to detail, it is clear that the direction of primate evolution has been toward greater adaptability rather than greater adaptation.

The point to be emphasized is that the essential step in the differentiation of the hominids occurred well before any substantial increase in brain size had occurred. Indeed, if the pebble tools found in association with the australopithecines are, in fact, products of their manufacture, tool making occurred at a brain size only slightly larger than that of the chimpanzee or orangutan and was followed by a 3- to 4-fold expansion of the brain.

The role of bipedal locomotion. The most important single factor in the evolutionary emergence of hominids as a separate and independent line is the development of erect bipedal locomotion. The pongids, on the other hand, developed a markedly different specialization toward the brachiating mode of locomotion. In the hominids, the lower limb increased in length in relation to trunk and upper limb; in the pongids, it was the upper limb that increased in relative length. In the hominids, the bones of the foot and the knee joint were modified for structural stability; in the pongids, mobility at these joints was enhanced for prehensile function. Far reaching changes occurred in the hominid pelvic girdle because of the demands of erect posture; the pelvis of the pongid retained the general shape and proportions found in lower primates. Although muscle structure can only be inferred from fossil remains, studies on contemporary species show marked differences in muscular anatomy between ape and man.

In a recent article, Hewes has suggested that habitual food carrying may have made bipedalism advantageous. He bases his thesis on observations of troops of Japanese monkeys, in whom a new loco-

motor habit could be observed to emerge as part of a chain of behaviors initiated by a new food supply. The monkeys had to walk some distance from the forest edge and return, carrying the food in their forelimbs, in order to eat in safety. In any event, Leakey's finds in the Olduvai Gorge suggest that the australopithecine was a "habitually bipedal plantigrade primate"—that is, an animal that walked on two legs and put its feet flat on the ground. Fossil fragments indicate that the hind limbs are more sapiens-like than the forelimbs. The development of a prehensile hand includes elements that are both peripheral (form and proportion of bone and muscle) and central (cortical sensorimotor mechanisms with increased cerebral representation of thumb and forefinger).

The roles of the hand and the brain. The question of whether hand or brain took the lead concerned Aristotle. On teleological grounds, Aristotle concluded:

Now Anaxagoras has said that it is the possession of hands that made man the most intelligent of animals. The probability is that it was because he was the most intelligent that he got hands... if it is best that it be so, and if nature, out of what is possible, always does what is best, it is not because he has hands that man is wise, but because he is the wisest of animals that he has hands.

Recent evidence, not available to Aristotle, appears to have settled the question in quite the opposite direction.

Tool making has been regarded as an essential characteristic of man, so much so that Benjamin Franklin suggested the name *Homo faber* for the human species. How unique are tools? Animals other than primates use tools; the sea otter smashes clams on rocks held against itself. In Napier's classification, this constitutes ad hoc tool using—that is, the use of an object available at the time. Goodall has recently provided evidence of purposeful tool using in the chimpanzee. These animals will soak up water in a clump of leaves, which are then brought to the mouth and squeezed. Moreover, she has photographic evidence of ad hoc tool modifying: for "termite fishing," the chimpanzee will walk some distance from the termite hill, pick a slender stalk and strip off side branches, return and thrust the stalk into the flight hole of the termite hill. When withdrawn, it is covered with termites and passed against the lips to deliver an avidly swallowed mouthful. There is as yet no evidence in animals other than man of tool modifying for future eventuality, of ad hoc tool making, or of the final stage, cultural tool making. Both ad hoc tool making and cultural tool making are evident from the eoliths found in association with *Homo erectus*.

The crucial step in the evolutionary sequence to man was the assumption of the erect bipedal posture, which freed the hands for the manufacture of tools and weapons. Tools have important consequences for the further development of the teeth, the jaws, and the powerful temporal and masseter muscles, which

in pongids are essential for the mastication of unprocessed and tough natural foods. Dental and mandibular changes occurred early in the evolutionary sequence to hominids. These structural and muscular changes, it has been suggested, may have permitted expansion of the cranium, which in the ape is confined by the massive attachment of the temporal muscles. Whatever the role of this intervening step, the manufacture of tools and weapons enhanced the survival value of central nervous system mutations, which permitted enhanced brain function, resulting in the manufacture of more effective tools, leading to a more elaborate social structure, and increasing the value of brain mutations, which permitted language development, etc. This lag of the brain behind other structural changes is also evident in the paleontology of the horse and may be a general principle in evolution.

Implications of an evolutionary view. Viewing the genesis of *Homo sapiens* from the evolutionary standpoint has important implications for the psychiatric study of modern man. By definition, the present characteristics of man are those that led to relative reproductive superiority. Modern man has existed for no more than 50,000 years after an evolution from primitive hominids over the preceding 1 million years or more; it is only the last 10,000 years, trivial from the standpoint of biological time, that have been characterized by an enormous technological and cultural efflorescence.

Man may have been left with biological traits that, though of positive survival value for conditions 50,000 years ago, may now be maladaptive for contemporary cultural conditions, at a time when man modifies his environment rather than himself. One example will illustrate this point. Stress responses, integrated through hypothalamic and limbic systems, initiate adrenal cortical and medullary activity, which leads to protein catabolism, enhanced blood coagulability, a differential shift of circulation, and enhanced carbohydrate mobilization. These anticipatory metabolic responses improve the capacity for muscular response to crisis. It has clear adaptive value in primates and in primitive man for fight or flight. But contemporary man continues to exhibit the same anticipatory mechanisms to culturally defined stress, to which an effective response is intellectual rather than physical. May not these physiological stress responses, repeatedly evoked by the complexities of urban civilization, play a role in the generation of arteriosclerosis and hypertension?

Postnatal brain development. The development of the human brain occurs predominately during postnatal life. This would appear to be a consequence of the size of the pelvic outlet that limits permissible brain size at birth. Man differs markedly from other primates in the proportion of brain development that occurs prenatally. Whereas the ratio of adult to neonatal brain weight is about 2.2 for the chimpanzee

and about 2.5 for the orangutan, the ratio for man is in the order of 3.5 to 4.0. The brain weight of the human infant is about 350 gm., about twice that of the infant chimpanzee, whose brain weight is about 170 gm.; but the adult brains are 1,450 and 375 gm., respectively. The difference is qualitative as well as quantitative. There is a 4-fold increase in the neocortex, a marked elaboration of the receiving areas for the teloreceptors, a disproportionate expansion of the motor area for the hand in relationship to representation for other parts, a manifold greater representation of tongue and larynx, and a great increase in the association areas. There is no homologue in other primates for the *speech* area found in man in the cortex; in contrast, *vocalization* can be produced by stimulation of the mesencephalic system in both species.

Although the gestation period is of the same order in higher apes and man, the postnatal maturation in man is greatly prolonged. Immaturity, and with it the disadvantage of dependency, is the purchase price for the greater adult adaptability attained through the increase in learning made possible by evolution of brain size and complexity.

Conel's histological studies of cerebral cortex in infants and young children have demonstrated the enormous growth in the number and branching of dendrites and the multiplication of synaptic junctions, all occurring while the organism is subject to shaping by the environment. The denseness of the feltwork of the cortex has made it impossible to detect structural changes in relation to experience, even if these do occur. Some recent experiments by Rose et al. indicated that growth of dendrites is a continuous process throughout life. They produced laminar lesions in the cortex of rabbits by monoenergetic heavy ionizing particles. By grading the radiation dose properly, they were able to produce a laminar zone of cortical tissue destruction without inducing cysts or scarring. Several weeks after radiation, sacrificed animals displayed a translucent zone without recognizable cellular structures. Companion animals allowed to survive a month longer and then sacrificed gave clear evidence of new fibers growing through the previously acellular zone. These studies provide the first evidence of structural growth in the central nervous system of adult mammals.

Evolution of social behavior. Among the adaptive mechanisms with biological significance for survival are behavior sequences. Behaviors that have a reproductive advantage lead to the selective multiplication of the organisms gifted with them. The basic mechanisms must be genic, but the genes concerned do not determine the behavior; rather, they determine the readiness with which it is learned. Part of this process is a selection for emotional states that make more likely the exhibition of adaptive behavior—that is, pleasure associated with the patterns evolution demands and fear toward maladaptive sequences. Per-

haps the best example is the supreme pleasure associated with the sexual act, an association that guarantees that all animals will seek to consummate the act on which the continuity of life itself depends.

What can be reasonably surmised about behavior mechanisms from the study of primate social behavior and from the study of Stone Age food-gathering and hunting societies? Primates live in groups with a surprisingly complex social order and division of labor, based on sex and age. The ubiquity of group behavior makes it clear that there must be genetic antecedents for the social learning that ties the individual to the group. Primates both young and old demonstrate marked differences in state when with and when separated from the tribe. Ethological observations of primate colonies in the wild have made clear the infrequency of full-fledged aggressive behavior within the group. Although there are differences by species and by colony, the over-all picture is one in which an elaborate social hierarchy is maintained by gesture and vocal threat so that destructive attacks within the colony occur rarely. Even the traditional image of the fearsome gorilla has to be abandoned after the observations of Schaller, who found him to be a remarkably pacific and gentle creature.

The social bond is fashioned initially out of the dependence of the infant on its mother and then from peer interaction. What Harlow has called "contact comfort" takes precedence in monkeys over the attachment to a nursing surrogate. But that this is based on the primacy of the grasp reflex in this species and that the grasp reflex is essential to survival are apparent when the mode of locomotion of arboreal primates is recalled. As the mother swings rapidly through the branches with the alternating use of her arms, the infant must have a genetic mechanism for clinging or be dashed to the ground.

Among the langur monkeys, the birth of an infant is an event of great attractive significance to other females, who will await a turn to handle the neonate under the watchful eye of his mother. The new mother, whatever her position in the general social hierarchy, takes precedence in governing accessibility to the infant. De Vore's field observations demonstrated that the adult male baboon is alert to distress cries by infants and young juveniles and defends them from attack; the dominant male, from whose proximity other adults flee, tolerates with surprising equanimity aggressive play and teasing by the young of the colony. Grooming behavior, reciprocated between mother and infant and between peers, is a major factor in fashioning the primate social matrix. Out of grooming, play, and the exchange of threats and gestures, strong social ties are fashioned, which maintain structured colony behavior. Although variations in the amount of aggression displayed, attributable to species differences and even to differences between colonies of a single species, are evident from field

studies, the most striking over-all characteristic of primate social behavior in the wild is the infrequency of intracolony physical attacks severe enough to produce injury, except under conditions of severe stress.

Among primitive peoples, all food-gathering and hunting societies exhibit the following characteristics: relatively open groups of 20 to 50 members, among whom relations are usually friendly; a kinship ethic that prescribes mutual aid (food sharing appears to be a *sine qua non* of the human condition); division of labor by sex and by domestic (family) units; rules to regulate patterns of mating and of competition; common language; a craving for response by each individual from his human environment, a craving that appears to be as fundamental as that for food. Although the modalities of interpersonal exchange become more and more complex with social evolution, the basic needs for recognition and acceptance by peers is everywhere evident.

The most remarkable trait of human social behavior is its *variability*. Aggression is no more fundamental or ubiquitous than is generosity. Freud's formulation—"The tendency to aggression is an innate independent instinctual disposition in man"—has no more scientific evidence to justify it than the misanthropic statement by Thomas Hobbes: "I put for . . . a general inclination of mankind a perpetuall and restlesse desire of Power after Power, that ceaseth only in death. . . . [This leads] to a time of Warre, where every man is Enemy to every man . . . no Arts, no Letters, no Society, and which is worst of all, a continuall feare and danger of violent death; and the life of man, solitary, poore, nasty, brutish and short." Both are statements of political philosophies. Freud, like Herbert Spencer before him, projected onto biology the socially derived characteristics of the civilization of his time (and ours). But that civilization is no more an immediate derivative of man's nature than the culture of the Pueblo Indian or the Alaskan Eskimo, to whom aggressive competition was unknown.

Development of the Individual

With the appearance of the human species, biological evolution has been superseded by cultural evolution. Man is the only animal capable of changing his environment in a planned—that is, future-oriented—fashion, though he does not always do it wisely or with a sufficiently long range view. All organisms change their environment—bacteria in consuming food and producing wastes, beavers in building dams—but most without the ability to anticipate or to plan for consequences. Man is the only animal capable of symbol use. Other animals communicate by signs and signals, but man alone possesses *symbols* that bind time. Language permits cognitive rehearsal, thinking through the consequences of action before attempting it. Language permits the abstraction of the general from the concrete and the realignment

of relationships between elements without dependence on actual or possible manipulation of the elements. By language, man can transmit the experience of the past generation to the young of the next and build continuously on his cultural heritage; this has led to the exponential growth of knowledge. Man's capacity to learn is of a different magnitude from that for any other species. Man surrenders built-in preadaptations (and hence is more vulnerable in infancy) for the capacity to adapt through learned responses in a wide variety of possible environments. This can be viewed as a choice of evolutionary strategies. These, then, are some of the issues to be faced in considering the development of the individual as the focus shifts from phylogeny to ontogeny.

Kessen's splendid collection of readings demonstrate that interest in the child as child has a cultural history. Until very recently, the child was viewed as an ill-formed or incomplete adult. The concept of childhood as a phenomenon unto itself, requiring special institutions for its preservation, is an invention of modern times. To quote Aries:

In medieval society, the idea of childhood did not exist; this is not to suggest that children were neglected, forsaken or despised. The idea of childhood is not to be confused with affection for children: it corresponds to an awareness of the particular nature of childhood... Language did not give the word child the restricted meaning we give it today.

Through the 18th century, the conditions of childhood were extremely precarious. Children born in London had by the end of that century only a 50-50 chance of reaching their fifth birthday; infantile death rates were on the order of 400 per 1,000. The factory system of the industrial revolution demanded cheap labor, and children were, in effect, sold into slavery. An "enlightened" law of 1833, passed over savage opposition, provided that children from 9 to 13 were not to work more than 48 hours a week and those from 13 to 18 not more than 68 hours. Even these minimal regulations did not apply to children working in mines until the Earl of Shaftesbury's crusade. Only with the writings of Locke and Rousseau did childhood begin to be thought of as an epoch important in itself. Rousseau's *Emile* or *On Education*, published in 1762, proposed revolutionary ideas: successive stages of development, the necessity for exercise of mental functions, adaptation to age-appropriate circumstances, and individuality in development. The first baby diaries were those of Tiedemann in 1787 and of Darwin on his firstborn son, William Erasmus, in 1840.

Darwinism revolutionized the concepts of psychology. The theory of evolution provided a mechanism for the doctrines of perfectibility heralded by the Encyclopedists of the French revolution. As homologies were sought between the phylogenetic progression of species and the development of individual man in society, comparative psychology was founded, and sociology and anthropology were profoundly in-

fluenced. Man was to be understood, not by an analysis of his adult functions, but by a study of his origins—in the scale of nature and in the child.

Prenatal factors. The analysis of individual development customarily begins with birth. However, significant experiential factors influence intrauterine development. It has been shown that intrauterine curare will lead to ankylosed joints in the sheep; movements of the limbs in utero are important factors in maintaining joint mobility. The administration of androgenic hormones in the effort to prevent miscarriage alters sex differentiation in the infant. Maternal stress, through the production of adrenal hormones, may influence the behavioral characteristics of the newborn. These few examples point to the wide range of potentially significant findings from a still uncharted area of investigation.

Complications of pregnancy and parturition are precursors of prenatal and paranatal injury to the central nervous system of the infant. Pasamanick and Knobloch have introduced the important concept of a continuum of reproductive casualty extending from miscarriage and stillbirth through cerebral palsy, mental retardation, and epilepsy to learning and behavior disorders—that is, extending from lethal injury to the central nervous system to minimal brain damage without obvious neurological impairment. The prevalence of these disorders (both the pregnancy complications and the clinical psychiatric manifestations) displays a distribution that is differential by social class and related to the relative adequacy of nutritional, medical, and general hygienic factors associated with class status. In no area of psychiatry are there clearer implications for preventive measures. The decision to apply what is known and the social action to make it available without distinction of class and race could result in a significant reduction in neuropsychiatric morbidity.

Infant stage. Once normal birth has occurred, to quote William James, "the baby, assailed by eyes, ears, nose, skin and entrails, all at once, feels it all as one blooming, buzzing confusion." How does this essentially brain stem preparation—the anencephalic infant behaves much like the normal newborn for the first 4 to 6 weeks of life—progress to the highly encephalized adult? Brain stem organization itself is different at birth from what comes into being with progressive differentiation of superordinate structures. The survival systems—breathing, sucking, swallowing, and circulatory and temperature homeostasis—are relatively functional at birth. But sensory systems are only incompletely developed; sensory impulses register at thalamic levels with no evidence of specific cortical responses. Further differentiation of neurophysiological functions depends on stimulatory reinforcement and is not an automatic consequence of the genomic structure.

Stimulus deprivation. The experiments of Riesen on chimpanzees reared in total darkness demon-

strated atrophy and up to 90 per cent loss of retinal cells if the animal is maintained in the dark for 2 years. The possibility of reversibility is lost after 5 to 7 months of total darkness. Rearing in diffuse light, by placing ground glass goggles over the eyes, results in poor eye movement control and poor fixation, consequences that become irreversible with the passage of time. In children with strabismus severe enough that images fall on nonequivalent parts of the two retinas, the image from one eye is suppressed; if left uncorrected to the age of 6, there is an irreversible loss of sight in the suppressed eye, amblyopia ex anopsia.

Hubel and Weisel have carried out a series of studies with microelectrode recordings from single cortical cells in the occipital lobes of kittens. At the earliest age, the investigators were able to identify cells responsive to the orientation of stationary linear light fronts—horizontal, vertical, or oblique—and to light fronts moving either from left to right or from right to left. That this organization is intrinsic is evident from the demonstration of these properties in newborn kittens with no visual experience. However, after 3 months of light deprivation in one eye, with the other eye maintained as a control, the kittens display functional blindness in the deprived eye, with no visual fixation, despite normal pupillary response and normal electroretinogram. At the level of the lateral geniculate, there is a 40 per cent shrinkage in cell mass. In the occipital lobes, there is an almost total absence of response in cells driven by the monocularly deprived eye. Here is an instance of the loss of functional interrelationships already present at birth but dependent on patterned stimulation for their maintenance. More recent unpublished work by these investigators indicated that the loss of functional representation in the cortex for the deprived eye is determined by the locking in of these units to the effective field of the normal eye; that is, if both eyes are deprived of visual experience, *neither* demonstrates much loss in its subtenant cortex, but *binocularly* driven cells are no longer evident. Moreover, if amblyopia is produced by severing the lateral rectus muscle in the eye of the newborn kitten, it sees well with either eye (and shows corresponding occipital electrical activity) but shows neither binocular vision nor occipital cells driven binocularly.

Simple passive visual experience is not enough for the acquisition of visual-motor coordination. Held and Hein have demonstrated that the development of visual placing responses and the ability to discriminate moving from stationary objects is a function of active exercise. In their studies, paired experimental kittens were exposed to a lighted environment for brief periods each day. One member of the pair is allowed to walk freely through the lighted environment; the second member is yoked to the first in such a fashion that he experiences the same translation through space but without the possibility of controlling his own move-

ment. Only the kitten who does the active exploring develops normal visual responses. The development of intersensory integration is an active, not an automatic process. The organism begins with its initial given capacities, and these are differentiated and interrelated via exercise so that higher order capabilities emerge.

In the terminology of Piaget, there are two fundamental processes at work: assimilation and accommodation. Assimilation is the process of utilizing and incorporating stimulus elements in the environment, just as the organism utilizes foods. Although Piaget used the term "aliment" in a figurative sense, it is remarkably descriptive of the visual experiments in which maintenance of the very integrity of the neurons in the optic system depends on external stimulation for alimentation. In assimilation, the organism takes in the new in terms of the familiar and acts in the present as it has in the past. In the process of accommodation, the organism is modified by the demands—that is, the novelties—of the environment. Accommodation leads to a reorganization of the programs of the organism as it struggles to cope more effectively with the mismatch between its available action patterns and the new requirements of its current environment.

Development of the social bond. As sensory development progresses, there is for all social organisms a parallel task of fashioning a tie between the newborn and its species. In recent years, much attention has been focused on the concepts of ethology. Ethologists have demonstrated, primarily in birds but also in ungulates, that there is a critical period shortly after birth in which the newborn becomes "imprinted" on a moving, sound-producing object that from then on serves to elicit following behavior, just as the mother does in the natural situation. Birds imprinted on artificial objects become isolates from the flock and may be unable to mate. For all of the undoubted importance of imprinting in certain species, it should be emphasized that imprinting has not been demonstrated in man or in other primates.

The effects of total social isolation in subhuman species are of great interest in studying the socialization process. Puppies isolated in individual cages for 6 months exhibit a peculiar syndrome characterized by overactivity, distractibility, inadequate response to pain, whirling fits, inferiority to pet-reared and colony-reared dogs in problem solving and in food competition, and inability to be effectively socialized thereafter. Monkeys reared as isolates, even when offered surrogate mothers (objects for clinging), are subsequently unable to adjust to a colony existence and have extraordinary difficulty in learning to mate. When impregnated, isolate-reared females fail to mother their young. The behavioral peculiarities of these isolates were initially attributed to the lack of mothering in infancy, but Harlow's more recent studies have demonstrated that an opportunity for

peer interaction between two nonmothered infant monkeys apparently suffices for the development of social behavior.

Harlow traced five affectional systems in the development of the monkey: infant-mother; peer; heterosexual; maternal; and paternal. The infant-mother affectional system is modulated via body contact, clinging, nursing, rocking, warmth, and visual stimulation. It passes through four stages: reflex, attachment, security, and separation. The peer system exhibits successive stages of presocial exploration, interactive play, aggressive play, and developing social status. Heterosexual differentiation includes the passivity pattern and pelvic thrusts of the female; the threat pattern, pelvic thrusts, and clasps of the male; grooming behavior; and full adult sexual behavior. The maternal affectional system develops through stages of attachment and protection, ambivalence, and separation and rejection. The paternal system includes such behaviors as retrieval, protection, and punishment.

Schneirla and Rosenblatt, in studying the suckling behaviors of kitten and cat, have emphasized the interactive nature of the developmental process. The maturation of the kitten, its acquisition of experience, and the interactions of the behaviors of kitten and cat contribute to the sequence. The suckling period, some 60 days in the cat, can be divided into three phases. In the 1st to the 20th day, the female approaches the kittens, arches her body in a "U" to present the mammary surface, and licks and so orients the kittens toward her. In response to tactile stimulation, the kittens acquire increasing skill in nipple localization and suckling. During the second phase, from the 20th to the 30th day, both the kittens and the cat initiate approaches. The kittens display increasing perceptual organization and orient to the home corner of the cage and to the cat. The cat responds with a "U" to the approach of the kittens. The kittens begin to play with one another. During the third and final phase, from the 30th to the 60th day, most suckling occurs at the initiative of the kittens, who pursue the mother vigorously. The cat now responds irregularly and avoids the kittens more and more until she no longer accepts them. Summarizing their findings, Schneirla and Rosenblatt stated:

These considerations favor a very different view of the concept of critical periods from the one now held by many writers. In the social development of the cat... striking changes in the essential progression are grounded not only in the growth-dependent processes of maturation but also, at the same time, in opportunities for experience and learning arising in the standard female-litter situation. This conception of social ontogeny encourages stressing not just one or a few chronologically marked changes in the behavior pattern, but rather indicates that normally each age period is crucial for the development of particular aspects in a complex progressive pattern of adjustment... critical periods in social development are not matters of maturation *per se*. Rather, time-conditioned factors depending upon experience in the normal situation, in close conjunction with growth-dependent factors, are necessary for both

the turning points and the intervening progress in social adjustment... Mammalian social development is thus seen as advancing from birth in ways that, for the species-characteristic outcome, continuously require not only the standard conditions of organic maturation but also the presence of the standard developmental setting with its progressively changing behavioral properties.

Social deprivation syndromes. What happens to the human infant deprived of normal social and cognitive experience? Pediatricians have long known and repeatedly recorded the severe developmental retardation that accompanies maternal rejection and neglect. Infants in institutions characterized by low staff-to-infant ratios and frequent turnover of personnel, even when physical care and freedom from infection are adequate, display marked developmental retardation. The same infants, if placed in adequate foster or adoptive care, undergo marked acceleration in development. Bowlby, in 1952, on the basis of an extensive review of the literature, concluded that early separation had persistent and irreversible effects on personality and intelligence. The most persuasive evidence for this conclusion was that provided by Goldfarb, who compared the behavior in adolescence of two groups of children abandoned in infancy. The first group remained in an orphanage for the first 3 years of life and then were placed in foster care; the second group were placed in foster care in infancy. The foster homes for the two groups were said to be substantially alike; the possibility of differential placement because of the initial characteristics of the infants was denied by the social agency. As adolescents, the children institutionalized for the first 3 years showed lower I.Q.s, inferior school performance, and sociopathic traits. Bowlby's later studies of children who had been separated from their families early in life because of tuberculosis failed to confirm the anticipated severe psychological consequences. Such factors as the quality of institutional care, the care received before and after institutionalization, the reasons for removal from the family, and the maintenance of a relationship with parents by visiting during the period of separation are important variables in determining outcome.

The most striking evidence that early damage can be reversed by adequate subsequent care was provided by the studies of Skeels. He identified 25 children in an orphanage, 13 of whom were removed for placement in an experimental program. They were placed in the care of older female retardates as foster mothers and were enrolled in a preschool enrichment program. Two years later, the experimental group, with a mean initial I.Q. of 64.3, had attained an I.Q. of 91.8, whereas the control group left in the orphanage, initially at 86.7, had declined to 60.5. Eleven of the 13 experimental children were adopted. Three years later, their mean I.Q. was 95.9, compared with 66.1 for the controls. Current information on the adult adjustment of the study subjects revealed that all 13 of the experimental children are self-supporting, and

11 are married and parents of 9 normal children. This group had attained a median education of 12th grade. In contrast, the 12 controls had a median third grade education. One had died in adolescence, 1 is in a mental hospital, 4 are in institutions for the retarded, 3 are unemployed, 2 are unskilled laborers, and only 1 is a skilled worker. The median cost to the state for the experimental program was about \$1,000 a child; the control group, most of whom remained in care throughout their lives, had cost from \$7,000 to \$24,000 each.

Bowlby's monograph on maternal deprivation, reviewed and critically assessed by a later World Health Organization publication, served to call attention to the disastrous and far reaching effects of early neglect. Its stress on the irreversibility of the damage was unfortunate; the early studies confounded the effects of separation and institutionalization with the poor care provided the children once they were removed from the initially depriving situation. The consequences of deprivation vary with the severity and duration of the depriving experience, the age of the child at which the deprivation occurs, and the adequacy of restitutive measures.

Temperamental differences. But what of the normal newborn in his own family? Is he a *tabula rasa*, a smooth slate on which characteristics are engraved with greater or lesser ease? Though a definitive answer to this question is not possible with present evidence, there are strong suggestions of congenital differences. Lipton et al. and Bridger have demonstrated wide individual differences among infants in autonomic reactivity, differences that persist over the newborn period but whose long range consequences are not yet known. The studies of Thomas et al. have demonstrated temperamental characteristics already evident by the 3rd month of life. In a careful longitudinal study of 130 middle class infants, the researchers were able to identify nine behavioral dimensions on which reliable ratings can be obtained: activity-passivity; regularity-irregularity; intensity; approach-withdrawal; adaptive-nonadaptive; high-low threshold of response to stimulation; positive-negative mood; high-low selectivity; and high-low distractibility. The ratings on individual children showed substantial correlations between 3 months and 2 years but much lower correlations at 5 years. During the course of the study, 27 of the children presented clinical psychiatric problems. Chess et al. were able to discern a relationship between the initial characteristics of the infant, the mode of parental management, and the subsequent appearance of symptoms.

Clinicians are coming to the view that the infant is an important actor in the family drama, one who in part determines its course. The behavior of the infant serves to control the behavior of his mother, just as her behavior modulates his. The calm, smiling, predictable, good infant is a powerful reward for ten-

der maternal care. The jittery, irregular, irritable infant tries a mother's patience; if her capacities for giving are marginal, his traits may cause her to turn away from him and thus complicate his already inadequate beginnings.

Cognitive development. At birth all infants have a repertoire of reflex behaviors—breathing, crying, defecating, head turning toward the stimulated cheek, mouthing of a nipple touching the lips, sucking, and swallowing. Recent studies have indicated that both vision and hearing are more highly developed in the newborn than they had been thought to be. By 1 to 2 weeks of age, the infant "smiles"; this response is endogenously determined, as evident by smiling in blind infants. By 2 to 4 weeks of age, visual fixation and visual following are evident, behaviors that may be compared to the following movements in subhuman forms. By 4 to 8 weeks, social smiling is elicited by the face or voice of the caretaker. By 16 to 18 weeks, vocalization or babbling has appeared in the child in a language-rich environment. The persistence and further evolution of this vocalization depend on rewarding consequences from the human environment. By 18 to 20 weeks, selective social smiling is apparent to familiar faces. This smile has been shaped by the response of adults and is in turn a powerful mechanism for controlling the adults. By 6 to 8 months, the child sits; by 9 to 12 months, he stands; and between 12 and 15 months, he usually walks and speaks his first words. Details of the sequence of motor and adaptive behaviors exhibited by the normally developing infant have been described by Gesell, whose scales permit comparison of the accomplishments of a particular infant with normative standards.

In contrast to the normative approach taken by Gesell, who views development as the unfolding of a genetically determined sequence, is Piaget's epigenetic theory of intelligence, summarized recently by Flavell. To Piaget, intelligence is but a special instance of biological adaptation within the context of life, which he views as a continuous creative interaction between the organism and its environment. The outer manifestation of this interaction is coping behavior; the inward reflection is the functional organization of the mental apparatus. Adaptive coping continuously reorganizes the structures of the mind. This theory is dissonant with most philosophical systems since Plato, which take the logical structures of space, causality, and time as given rather than as evolving epigenetically.

Piaget divided the development of intelligence into three major periods: sensorimotor, birth to 2 years; concrete operations, 2 to 12 years; and formal operations, 12 years through adult life. The sensorimotor period is one in which the congenital sensorimotor schemata or reflexes are generalized, related to one another, and differentiated to become the elementary operations of intelligence. The period of concrete oper-

ations is divided into a preconceptual phase, from 2 to 4 years of age, during which symbols are constructed; the intuitive phase of acquiring concepts of space, causality, and time, from 4 to 7; and the phase of concrete operations, in which thought becomes de-centered from perception and action—that is, the increasing autonomy of central processes permits the activities of classifying, ordering, and numbering. The period of formal operations is one of systematization and recombination of the concrete operations, in the course of which the logical structures of abstract thought are mastered.

A review of the first few stages of the sensorimotor period may serve to convey Piaget's method of analysis. In its first stage, from birth to 2 months, the exercise of the ready made reflexes leads to a transition from passive release by stimulation to active groping. Reflex sucking is accompanied by search and discrimination; vision moves from the pupillary reflex response to light to following and active search; prehension moves from the grasp reflex to separate finger movements. The exercise of a function brings inherent satisfaction or what Buhler called function pleasure. This notion of function pleasure is to be distinguished from the widely held concept that the satisfaction of a physiological need is the governing principle of behavior. The varying circumstances of stimulation during this period promote accommodation of the organism to the necessities of the external world; that is, the infant shapes his response to the particularities of the simulating object—be it finger, nipple, or spoon—and, in so doing, changes himself.

The next stage, primary circular reactions, from 2 to 5 months, is one of reciprocal coordination between the hand and the sucking movements of the mouth, between the hearing and the seeing of a visible and audible object, between the seeing and the grasping of a visible and palpable object, etc. New objects elicit greater interest than overly familiar ones. Recent studies have demonstrated that infants will view complex patterns for longer periods than they will simple patterns. As the infant's hands come into his visual field by chance, he stares at them and then begins to move them as he watches them. Something looked at becomes something to grasp, and something grasped becomes something to suck. However, at this stage reality remains subjective—that is, there is no further search for an object that disappears from the visual field. The child has no general space but only a buccal, a kinesthetic, a visual, an auditory space.

The third stage, secondary circular reactions, from 5 to 9 months, is one in which the coordinations of the second stage become dissociated and regrouped in new ways and acquire the independence of learning sets. The rudiments of intentionality appear as the child begins to anticipate the consequences of his own acts. The infant no longer merely utilizes adventitious circumstances but begins to bring definite actions to

bear on these circumstances. Ends, the outcomes sought, are differentiated from the means, his own actions. The infant dandled on his father's knee will begin to bounce up and down when the knee stops, as if this were intended to cause the knee to bounce him. Recognition is manifested by outlined or abbreviated acts. Thus, the infant who had enjoyed the movements of a toy brought about by the shaking of his legs will briefly shake his legs when he sees the toy again. It is at this stage that the elementary constructions of reality are undertaken. Objects begin to acquire permanence. Prior to this point, the rest of the world exists for the infant only insofar as it impinges on his sensations or is subject to his actions. Once removed from his immediate presence, objects have no further meaning for him. But, now, if an object is dropped in front of him, he will look down to the ground to search for it; that is, he behaves for the first time as though the object had a reality outside of him. Although true object permanence is not attained until well into the 2nd year of life. Another important acquisition in this stage is the beginning of imitation.

The remaining stages of the sensorimotor period—coordination of the secondary schemata, the tertiary circular reactions, and the invention of new means through mental combination—cannot here be described, nor can the periods of concrete operations and formal operations. They will, however, repay careful study in Flavell's synthesis of Piaget's many volumes or, better yet, in the originals. Piaget has emphasized throughout the role of intervening experience on the maturation of cognitive functions. It is the richness, complexity, and diversity of stimulation in a favorable environment that results in the accommodation of mental structures to the nuances of reality and in the elaboration of the highest mental functions. Although Piaget's studies have until recently been limited to normal children of favorable circumstance, the framework he developed is a useful one in cross-cultural and cross-class comparisons. Currently, there are active efforts to develop intelligence tests based on the Piagetian scheme of the epigenetic development of intelligence.

Emotional development. Parallel to the stages of cognitive development are the stages of emotional development. Despite the conventional practice of separating them, they are clearly interdependent. Indeed, it is the care-taking person who provides the major stimulus to both aspects of mental growth. The human infant is totally dependent on adult care-takers for sheer survival. It is in relation to regular and hence predictable events of care-taking that an affectional tie between infant and care-taker develops; his behavioral repertoire expands as his acts have consequences in the form of social responses from the care-takers.

The Freudian formulation that the tie to the mother develops solely or principally by extension from the

nursing act takes far too restricted a view of the interoceptive and exteroceptive channels stimulated by mothering and important to the sensory hierarchy of the infant. Contact does not play the role in the human infant demonstrated by Harlow for the monkey, but touch, smell, sight, sound, warmth, kinesthetic stimulation, and the infant's own behavior do enter into the complex of care. As perceptual and cognitive maturation occurs, the infant is able to relate these initially disconnected and separate experiences to the person who provides them and to distinguish her from other persons in the environment.

The severity of the effects resulting from deprivation of mothering care attests to the central role of mothering—and *fathering*—in the normal developmental process. However, just as with Bowlby's initial view that irreversible harm results from early lack, Erikson's concept that a sense of trust—confident expectation that needs will be met—is elaborated primarily from need satisfaction in the *1st year* of life is one-sided and incomplete. The basis for trust in others *begins* to emerge from good care in infancy, but trust is in *no* sense a final acquisition of this 1st year and must be continuously reinforced during all of childhood and adolescence if it is to become a prevailing trait. A more accurate formulation would be that the nucleus of trust is established in infancy but that the issue is far from settled.

Toddler stage. The 2nd year of life is marked by acceleration of motor and intellectual development. The ability to walk confers on the toddler a degree of control over his own actions that allows him to determine when to approach and when to withdraw. The acquisition of speech profoundly extends his horizons. Typically the child learns to say "no" before he learns to say "yes." Correspondingly, the infant knows what he doesn't want long before he is able to formulate what he does want. The negativism of the toddler is a vital stage in individuation. "It is useless to be able to do what one cannot stop doing," noted Lao-Tse.

The 2nd and 3rd years of life are a period of increasing social demands on the child. The clinical observation that toilet training can become a focus of struggle between mother and child has led to the simplistic formulation that toilet training in itself is a critical event for character formation. The prolific literature on this subject implies that training is inevitably a traumatic event, but this is a distorted formulation based on one-sided experience with disturbed families. It *can* be elevated to a central issue by a rigid, severe, and restricting mother, but it varies with the culture and with the temperamental characteristics of mother and child. The fortunate mother whose child has regular bowel function with predictable evacuations can train him with a minimum of effort, in contrast to the potential for trouble provided by an irregular youngster. When toilet training problems are associated with clinical psychiatric dis-

orders, it is not necessarily because of the toilet training itself but rather because toilet training serves a paradigm of the general training practices of the family—that is, the mother who is overly severe in this area is likely to be punitive and restrictive in others as well. Thus, what appears to be a consequence of toilet training is a consequence of general child-rearing practices, of which this is only an instance. The child's ability to accommodate himself to social demands by the acquisition of self-control can lead to pride in self and zestful striving for a new accomplishment; if he surrenders to parental coercion with shame at his physiological functions and doubt as to his own worth, he emerges inhibited, fearful, and stereotyped; if he rebels, he may remain stubborn and oppositional.

Parallel to the changing tasks for the child are changing tasks for his parents. Whereas in the stage of infancy the major responsibility for parents is to meet the infant's needs in a sensitive and giving fashion, without so anticipating and so fulfilling his needs that he never experiences tension, the parental task at the toddler stage is a requirement for firmness about the boundaries of acceptable behavior and encouragement of the progressive emancipation of the child. The child must be allowed to do for himself insofar as he is able, but he must be protected and assisted when the challenges are beyond him.

In the 4th year of life, there is further augmentation of the youngster's capacities, which, however, still run well behind his aspirations; he often undertakes things he cannot complete successfully. He becomes capable of anticipation as a basis for accepting the postponement of immediate gratification. There is a flowering of imagination, as revealed in controlled fantasy and play. Play is a central psychological activity for this period. It is, to begin with, fun: the sheer pleasure of exercising new executive capacities and acquiring mastery. It serves the function of releasing tension and energy. Following stress, it can provide emotional catharsis. But perhaps most important of all, the trial roles assumed in dramatic play allow the child to try out the adult identities he will one day have to understand and to assume. It is during this era that sexual identity is firmly established.

Psychosexual development. The forerunners of sexual differentiation are evident from birth when parents dress infants differently and treat them differently because of the differential expectations evoked by sex typing. The child through imitation, reward, and coercion assumes the behaviors that his culture defines for his sexual role. The way he walks, talks, and gestures; the level of activity he is permitted; the games he plays—all are differential by sex, and all serve to identify him to others and to tell him about himself as his role becomes crystallized. He exhibits active curiosity about anatomical sex. If this curiosity is recognized as healthy and is met with

honest and age-appropriate replies, he acquires a sense of the wonder of life and comfort about his own role in it. If the subject is taboo and his questions rebuffed, he responds with shame and discomfort.

At this stage he is likely to struggle for the exclusive affection and attention of his parents. This includes both rivalry with his siblings and with one or another parent for the star role in the family. Although he is beginning to be able to share, he gives up only with difficulty. Psychoanalysis has emphasized the competition for the exclusive possession of the parent of the opposite sex and rivalry with the same-sexed parent, the oedipal conflict. Here again, the elaboration of theory based on the study of disturbed patients—indeed, of adult patients whose recollections of early childhood are distorted by fantasy—has led to an unwarranted focus on the oedipal problem. It is more useful to conceptualize the developmental task as one of acquiring a comfortable sharing of love roles in the family rather than a distorted love affair with a parent whose response sexualizes the child's search for security and comfort. If the demands for exclusive possession are not effectively resolved, the result is likely to be jealous competitiveness in relations with peers and lovers. The fantasies aroused by the struggle lead to fear of retaliation and displacement of fear onto external objects. These issues are important in elaborating the basis for conscience. In an equitable, loving family, the child elaborates a moral system of ethical rights freely contracted. This contrasts with conscience based on terror, with fear of retaliation for unchecked cupidity, leading to ritualized and rigid moralism.

School period. As the child enters kindergarten and elementary school, the formal demands for academic learning, particularly in Western society, become major determinants of further personality development. So crucial is this task of developing competence that success or failure in it molds the child's image of himself as a capable and adequate person or as an inferior and feckless one.

Intelligence measurement. Although the child's "intelligence" as measured by I.Q. tests is the single variable that correlates most highly with academic success, the coefficient of correlation between I.Q. and grades does not exceed 0.6 to 0.7, thus accounting for no more than a third to a half of the variance. Equally salient are motivation, work habits, creativity, and other traits for which there are as yet no quantitative measures. There is impressive evidence that the disadvantageous circumstances associated with urban slum life depress motivation, measured I.Q., and academic accomplishment. Eisenberg reported, in 1966, that from a third to a half of children from urban slums are more than 2 years retarded in reading by the sixth grade, and the gap is even greater by the ninth grade. These are the youngsters who are likely

to drop out of school and to join the mass of chronically unemployable adults because of lack of salable skills.

Unfortunately, by a process of circular reasoning, the poor school performance is commonly explained by the poor I.Q., which is attributed to the genetic consequences of assortative mating—that is, the inferior academic accomplishments of slum dwellers are attributed to biological inadequacy. This viewpoint has been espoused at least since the time of Plato, who invented the myth of the men of gold, silver, brass, and iron as a useful falsehood to persuade citizens to accept their destiny in the state. In its contemporary version, its advocates justify the conclusion that the poor are inferior by pointing to their school performance, without recognizing the role of the inadequacy of the education provided to them in determining that performance.

The children of the urban slum, of migrant workers, of ghettoized minority groups are doubly disadvantaged. They arrive at school poorly motivated, unfamiliar with the academic materials that are commonplace in the middle class home, with short attention span, with language deficient in vocabulary and in syntactical structure, rich in survival behaviors suitable for the alleys of the city but highly inappropriate in school. Once they arrive, they are faced with schools that are overcrowded, obsolescent in physical structure, inadequately staffed, and frequently staffed by ill trained and poorly motivated teachers. Is it then a wonder that serial measures, both of I.Q. and of academic attainment, show a progressively widening gap between these children and those more favored?

Indeed, one of the most pernicious of myths is the notion of constancy of the I.Q. Though it is true that I.Q. measures on groups of children show remarkable apparent constancy over a period of several years, the scores for individual children within the group, even of middle class children, show wide variation. For example, in the Fels study of I.Q. from age 3 to age 12, two thirds of the children varied more than 15 points in I.Q.—and one showed as much as a 58-point change—despite a mean group I.Q. that remained at about 120. Noteworthy in these studies was the observation that children who at 5 displayed the traits associated with achievement motivation—independence, competitiveness, self-initiation—were among those likely to show I.Q. gains, whereas those low on these measures were characterized by declining I.Q. figures.

Indeed, all this was said by Binet, whose psychometric methods have been suborned for a purpose he deplored:

Some recent philosophers appear to have given their moral support to the deplorable verdict that the intelligence of the individual is a fixed quantity.... We must protest and act against this brutal pessimism.... A child's mind is like a field for which an expert farmer has advised a change in the method of cultivating, with the result that in place of desert land, we

TABLE I

Raw Scores for Head Start Subjects and Controls in Peabody Picture Vocabulary Test (PPVT) and Harris-Goodenough Draw-a-Person (DAP)

	Head Start						Controls ^a	
	First week of program		Sixth week of program		Two weeks after program		PPVT	DAP
	PPVT	DAP	PPVT	DAP	PPVT	DAP		
Mean.....	32.63	7.71	36.83	9.10	39.74	9.75	33.65	8.91
Standard deviation.....	12.33	4.79	10.82	4.20	11.34	4.41	11.70	4.98
Number of cases	(424)	(500)	(423)	(476)	(413)	(435)	(402)	(420)

^a Controls were tested 2 weeks after the end of the Head Start program.

Porteus Maze Test Quotient Scores before and after Treatment^a

	Drug		Placebo	
	Before	After	Before	After
Number of cases.	(19)	(19)	(19)	(17)
Mean	102.79	118.63	105.63	107.59
Standard deviation..	16.37	10.41	17.14	18.66

^a The drug given was a stimulant, either dextroamphetamine or methylphenidate. $t(df = 34) = 3.32$; $P < 0.01$.

now have a harvest. It is in this particular sense, the one which is significant, that we say that the intelligence of children may be increased. One increases that which constitutes the intelligence of a school child, namely, the capacity to learn, to improve with instruction.

That Binet was indeed correct is evident from the modification of cognitive performance by preschool enrichment programs for disadvantaged 5-year-old slum dwellers. In studies on Project Head Start in Baltimore in the summer of 1965, the Peabody Picture Vocabulary Test (PPVT) and the Harris-Goodenough Draw-a-Person (DAP), which correlate respectably with standard I.Q. measures on the usual population samples, were administered to the Head Start children and to a control group. On the PPVT, the controls and the Head Start children showed no significant difference on the pre-test, but the Head Start children showed improvement during and after the program (see Table I).

In the DAP, Head Start children also showed improvement, but the controls scored about the same as the Head Start children half way through the program (see Table I). This suggests either that the function tapped by the DAP matures with less dependence on outside stimulation or that the stimulus configurations necessary for its development are relatively more available in the slum environment.

The question remains: What has changed in relation to the Head Start experience? That the difference is not simply ascribable to test practice is suggested by test-retest data reported by others. That the effects are substantial and reproducible is indicated by the studies of Gray and Klaus and of Dunn and Mueller with children given longer enrichment experiences. It is not at all clear whether Head Start has improved understanding of instructions, involvement in the test situation, attentiveness, planfulness, familiarity with test materials and methods, hearing vocabulary, verbal intelligence, visumotor performance, or intellectual maturity.

The dependence of intelligence, that which cognitive tests attempt to measure, on such primary traits as the ability to sustain attention and to inhibit impulsive responding is illustrated by findings in the treatment of children with hyperkinetic behavior disorders with stimulant drugs (dextroamphetamine and methylphenidate). The patients were given Porteus Maze Tests before and after treatment by active drug or placebo in a double-blind design. As Table II indicates, the children treated by the stimulant drug showed a highly significant improvement in Porteus I.Q., whereas the placebo group showed no change. Was intelligence increased? Or did the drug, by diminishing impulsiveness, reveal the intelligence that was really there? Clearly, the answer depends on what is included in the definition of intelligence.

There is no innate intelligence. Intelligence is as intelligence does, for it is *behavior* that is measured. Intelligent behavior emerges from the interaction between the characteristics of the child and the demands and opportunities of his environment. These statements do not represent a denial of the reality of individual differences. The emphasis on nature or nurture in polemics on intelligence is a false issue. *All* behavior is inherited; *all* behavior is acquired. It is as meaningful to ask how much is inherited and how much acquired as it is to ask how much of the area of a rectangle is due to the length and how much to the width. There can be no behavior without both nature and nurture. The relevant questions are: With nature held constant, what is the variance produced by differences in nurture? With nurture held constant, how much variance can be produced by differences in nature?

Aggressive behavior. The frequency of aggressive behavior in children is often used as an argument for an innate aggressive instinct. Here is yet another instance of the widespread tendency to substitute for the actual study of infantile behavior the mere a priori assignment of motives on the basis of spurious analogies with adult motivations. In the normal child, aggression can be effectively understood in terms of the motives—defense, mastery, curiosity—for which aggressiveness is a suitable mediator. Its greater frequency in the abnormal child can be correlated with defects in the organism, as in the case of brain in-

jury, or with distortions in his environment, as in the case of faulty identification models. Moreover, the frequency of display of aggressive behavior is a function of the culture in which the child is reared. Aggressive fantasy materials—movies, crime comics, and so on—rather than affording catharsis for instinctual aggressiveness, generate the very tensions they profess to release. It is not the ubiquity of aggression that needs to be accounted for; it is its remarkably wide variation from culture to culture, from time to time in a given culture, and from individual to individual in a given culture at a given time.

A central issue is the meaning to be ascribed to the term "aggression." If a child is observed taking apart a watch, this behavior can be described as aggressive. In a given instance, it may be—if, for example, the watch belongs to the child's father, and the father has just punished him. On the other hand, if the watch is an old one in his stock of toys, his motive may be curiosity about its mechanism—a belief more readily accepted if his delight as he is able to reassemble it in working order is observed. If he strikes another child, this can be an act of aggression. It well may be if the victim is the baby sister his parents have just embraced. Or it may be defensive if the victim has made a threatening gesture or has tried to seize a favorite toy. Homely anecdotes serve to make the point, but documented experimental examples are readily available—children emulating adult models, children systematically subjected to frustration, children watching films of aggressive behavior—all of whom show predictable increases in aggressiveness.

The doctrine of aggressive instincts exhibits a curious indirectness of reasoning. All active behavior is labeled aggressive. The label is then taken as sufficient to represent the source. In so doing, this argument reflects the ambiguity of everyday language, in which aggressive is defined at one and the same time as "assaultive and violent" and as "energetic and vigorous." Surely, there is a world of difference between an assault intended to destroy and a vigorous effort to cope adaptively. To argue that the latter is but a sublimated equivalent of the former is to substitute mere verbal trickery for detailed behavioral analysis. The capacity for aggression is indeed inherent in the biological organization of man, as it is in all mammals; its display is, however, conditioned by other determinants.

Adolescence. Adolescence is a critical period of development, with manifestations at the biological, psychological, and social levels of integration; it is a period of variable onset and duration, marking the end of childhood and setting the foundation for maturity. Biologically, its onset is signaled by the final phase of acceleration of growth and the beginnings of secondary sexual development, and its termination is marked by epiphyseal fusion and the completion of sexual differentiation. Psychologically, it is marked

by an acceleration of cognitive growth and personality formation and is succeeded by the stage of parenthood and the acquisition of an adult work role. Socially, it is a period of intensified preparation for the assumption of an adult role, and its termination is signaled when the individual is accorded full adult prerogatives, the timing and nature of which vary widely from society to society.

Development at the biological, psychological, and social levels of integration is marked by significant interaction between levels, with events at any one level being able to impede or accelerate development at each of the others. Although the time at which the hypothalamic-pituitary axis initiates growth acceleration and sexual maturation is a function of individual heredity, it may be delayed or advanced by environmental factors. The ultimate height attained by adolescents in economically developing countries has shown striking gains as nutrition has improved—as, for example, in Japan since the war. Similarly, the time of menarche has shown a trend toward acceleration in countries with improving standards of nutrition and health; these physiological trends are the result of industrial and social organization.

In similar fashion, biological maturation provides the muscular strength and dexterity that permits the adolescent to participate successfully in the activities of his peer group, success at which promotes a psychological feeling of adequacy. At the same time, positive psychological motivation is a prerequisite for task perseverance and the search for variety of experience, which provides the conditions necessary for full muscular development through exercise. Folk beliefs about diet may lead to inadequate nutritional intake; social prejudices against minority group members may deny them the experiences necessary for full individuation. The importance of these reciprocal influences is underscored by the fact that each society is ultimately dependent on its adolescents as its future adults. Failure to provide the conditions necessary for their optimal development will handicap the growth potential of the society.

Biological factors. Biological factors set wide limits for the onset, termination, and achievements of adolescence. Onset in normal children may occur as early as age 7 or 8 or as late as 17 or 18; termination may be as early as 15 or 16 or as late as 24 or 25. The timing is a function both of internal factors, such as sex and inheritance, and of external factors, such as nutrition and medical care.

Social factors. Adolescence as a social phenomenon, though restricted by biological limits, is a function of cultural norms. The more sophisticated a society in its technology, the more prolonged the period of adolescence, since the complexity of the preparation required for adult roles depends on the demands the society sets. In the United States, the long period of study required for specialized occupational roles delays the age of self-support, the opportunity for

marriage, and the age of creative contribution to society—all attributes of the adult role.

In many cultures, the onset of adolescence is clearly signaled by puberty rites, usually in the form of tests of strength and courage. In technologically advanced societies, there is no such clear significance of the end of childhood; moreover, the requirements for adulthood are less sharply defined; the individual must undergo a more prolonged and, at times, confused struggle to attain adult status.

Psychological factors. At a psychological level, the most striking attainment during adolescence is the ability for abstract conceptualization. It is here that the foundations of scientific contribution and of creativity are to be found. The adolescent's capacity for abstract thought accounts for his increasing concern with national and international problems and with the basic meanings and values of human existence. This idealism of adolescents is shaped by the cultural envelope that surrounds the individual, but its very existence leads to questioning, to examination of basic premises, and to dissatisfaction with the imperfections in the world as it is. Fostering and strengthening this suprapersonal psychological trait in adolescence leads to the creation of adults who enhance the society that bred them. The denial of opportunity for its positive expression warps development and leads to a generation of self-preoccupied adults who may fail to meet the challenge of history.

A related theme of adolescence is the search for a sense of personal identity, in the cogent terminology of Erikson. No longer a child and not yet an adult, the adolescent engages busily in determining who he is and what he is to become. He examines his parents from a more critical perspective and leans more to peer groups for his sense of belonging. If his relations with his parents have been soundly constructed and if they meet his doubts and criticisms with sympathetic understanding, this temporary unsettling of his prior role leads to a resynthesis of his relations with them on a firm and lasting basis, one marked by reciprocal respect and by personal independence without abandonment of filial loyalty. Where the prior parent-child relationship has been one of excessive dependence or excessive hostility, adolescent turmoil may be prolonged and lead either to failure of emancipation or to rejection of family ties and a lasting sense of isolation.

A third major psychological issue is the further evolution of psychosexual role. The development of adult sexual characteristics and the experience of a bewildering array of new physical sensations, both of which lead to an upsurge of interest in physical sex and a psychological sensitization to a new aspect of interpersonal relationships, challenge the psychosexual structures of childhood. Comparative studies indicate that, as the scale of evolution is ascended, sexual behavior is less dependent on hormones and more dependent on learning. In man, the role of hor-

mones is limited to priming the organism for biological maturation and to influencing but not determining solely the level of libido; the direction, nature, and adequacy of sexual performance are controlled by psychosocial factors. The many investigations of the biology of sex deviants have failed to identify chromosomal, hormonal, or gonadal aberrations. The remarkable variation in sexual behavior between societies and between social classes within a single society emphasizes the cultural determinants of sexual behavior, given adequate biological maturation.

The ambivalence of Western society toward sexuality—manifested by the conflicts between official attitudes and private behaviors and the pervasive emphasis on sex side by side with sanctions against its expression—contributes to the difficulty, so common in adolescence, of attaining the basis for a sense of competence, freedom, and pleasure as a sexually functioning adult. Adolescents are entitled to full and unambiguous information about the physiology of sex and its ethical significance as an intimate relationship between human beings. Commonly expressed fears that providing such information to adolescents will lead to premature experimentation run contrary to clinical experience, which indicates that ignorance of sex and impoverishment of human relationships account for sexual misadventures. A sense of inadequacy in sexuality not only impairs sexual function but leads to disabilities in other adult roles.

The search for identity is markedly influenced by peer groups. If these are constructive social groups that provide creative outlets for adolescent energy, the result is a sense of meaningful membership in the community and identification with its goals. But if the peer group is a delinquent gang, with values antagonistic to the larger society, the result is likely to be antisocial personality organization. The experience of growing up as a member of a disadvantaged minority group, with attendant humiliation and denial of opportunity, makes it difficult for the adolescent to identify with the values of the society at large and favors instead hostility toward its norms and a disposition to anarchistic individualism. However, even under these circumstances, leadership and social forms that permit the disadvantaged adolescent to employ his energy in efforts to change unjust social patterns can foster his emergence into creative adulthood.

The *family* is an important agent in transmitting the behavior patterns and values expected of the adolescent by society. Distortions in family structure, whether idiosyncratic or socially induced, inevitably have profound effects on individual development. The social consequences of economic disadvantage—poor health, reduced longevity, poor education, extralegal marital arrangements, the necessity for exploiting children economically—erode family structure. The unemployed drifting father and the unmarried de-

served mother not only fail to provide their children with adequate nurture but also serve as poor identification models. The aggregation of disadvantaged families in decaying neighborhoods all too often reinforces family psychopathology by exposing the adolescent to delinquent gangs and ineffective schooling.

The sensitivity of the adolescent to the good opinion of his peers and the dependence of his sense of identity on the attainment of competence in an adult role render him psychologically vulnerable to variations in physiological development, such as precocious or delayed growth, acne, obesity, enlarged mammary glands in the males, and inadequate or overabundant breast development in the female. These deviations from expected patterns of maturation, though they may be without great medical significance, can lead to major psychological harm if not offset by sensitive guidance by the physician. The adolescent with limited intellectual or physical capacity can develop a persisting and even unchangeable feeling of inferiority if he is forced to compete in situations in which he repeatedly experiences failure. The individualization of education and vocational training for adolescents is essential, both to permit the talented individual to exploit his abilities and to direct the youngster with specific limitations to activities that develop the capacities he does have.

The characteristic fluidity of psychological structure in adolescence results in the common display of transient symptoms, many of which resemble the psychopathological syndromes of adulthood. The clinician must exercise great caution lest he misinterpret the turbulent but temporary maladaptive patterns manifested by the adolescents. Incorrect diagnostic formulations may lead to social consequences that freeze into permanence an otherwise readily correctable deviation in the normal growth pattern. It is, of course, true that schizophrenia and manic-depressive psychosis appear at significant rates for the first time in adolescence. However, these remain relatively uncommon disorders and must be discriminated from panic states in a youngster confronted by overwhelming internal and external stimulation.

The psychological basis for a sense of individual worth as an adult rests on the acquisition of competence in a work role during adolescence. A sense of competence is acquired not by being reassured but by experiencing success in a socially important task. The educational challenge is to stimulate abilities to the utmost without setting standards so high that they lead to inevitable defeat. The educational accomplishment must be matched by an opportunity for the individual to exercise his competence as a worker in the economic world. The sustained motivation necessary for mastering a difficult work role is only possible when there is a real likelihood of fulfilling that role in adult life and of having it respected by others. The task of providing full employment in a world in

which automation is revolutionizing traditional work roles is a challenge to the citizenry and the government.

The capacity for engagement in meaningful social activity is present in young people in every country of the world. For all the dismay caused by the disengagement and alienation experienced by many American adolescents, the dedication, zest for life, and commitment displayed by workers in the Peace Corps, VISTA, and the civil rights movement give us faith that this is a generation better than our own. The provision of an optimal framework for adolescent development is inseparable from the struggle to create a better world by helping to mold the citizens who will build it.

After adolescence. Development continues as long as life continues. As social roles change, as intellectual and physical capacities first advance and later recede, new challenges demand new adaptations. Studies of sensory deprivation in the normal volunteer have emphasized the role of sensory input in maintaining reality testing and perceptual organization. Social input is necessary for the maintenance of personality organization. What appear to be remarkable constancies of personality over a lifetime are not to be taken as evidence of a crystallized and unchangeable structure; rather, they result from the constant reinforcement of personality traits by the social environment in which the individual moves. Changes in the social field—brought about by chance, social change, or catastrophe—can lead to profound alterations in personal function.

The adult psychiatrist, no less than the child psychiatrist, must view his patient in dynamic terms as an organism with a history, with a set of attitudes and expectations, and with profound dependence on the forces in his social field. The patient should be assessed as much in terms of his abilities as his disabilities, as much in terms of what he can become as what he has been and what he is. Clinical diagnosis and treatment are most effective when based on a view that stresses personality as an emergent, constantly in the process of formation and never fully complete.

Chapter 39

Assessment in Child Psychiatry

39.1 PSYCHIATRIC EXAMINATION OF THE CHILD

J. FRANKLIN ROBINSON, M.D.

The psychiatric examination of a child is a step in a process in which the clinician is responsible both to the child and to his parents, who are ultimately accountable for the child. The patient unit consists of the child and his parents—a child in a family. Understanding the parents is as important as the direct examination of the child. Interviews with the child are the culmination of an evaluative process illuminated by historical information and an appraisal of the child's current adjustment. The evaluation includes psychological tests and measurements and physical examination, with indicated biological studies.

The psychiatrist usually encounters the child through his parents, who have initiated the move to seek help. Work is carried out with their approval and assistance. They have been intimately involved in the development of the difficulties over which they are concerned, and their feelings and attitudes influence the evaluative review. The clinician is in the unique position of carrying out a service for the parents as he endeavors to study and understand them. He must weigh the manner in which their personal needs and inclinations color the information they provide and estimate how they will influence steps that are to be undertaken in diagnosis, treatment, or management. Some of the most important information about parents derives from the manner in which they participate in the clinical procedures.

History

The parents. By the time some parents appear for psychiatric help, they are interested in learning how to proceed with treatment. They may have completed previous psychiatric or psychological studies. Compiling an extensive history seems to them superfluous and may divert them from their urge to approach their difficulties actively. When treatment is the immediate

aim of the parents and if the nature of the difficulty is evident, historical information can accumulate as interviews with the child and parents proceed on a scheduled basis.

In order to obtain a complete picture of the family, both parents must be included in the diagnostic study. With younger children it is common for mothers to present themselves alone for the initial interview. This is partly because it is more convenient for mothers who are not working to keep appointments during the business day and partly because mothers are more actively involved in the daily care of younger children. The readiness of each parent to participate in the early studies may yield information about the nature of the relationship between the parents and the manner in which difficulties with the children are approached in the family. Of special interest are discordant differences in their direction and management of the child.

Parents are not objective informants. Their account of the development and past events in the life of the child and their description of his current adjustment may be inaccurate. Distortion of factual information can be of significance in revealing the attitudes of the informant. Data obtained from the parents in separate interviews can be considered reliable if their statements correspond. Further verification may be obtained by consulting additional informants, such as grandparents or other relatives, teachers, etc. The establishment of reliability may be less important than the information that unfolds before the clinician as he observes the manner in which the parents proceed.

Technique. There is considerable variation among clinicians in the emphasis placed on the early compilation of an historical account and on the manner in which the parents react in the clinical process. With this dual interest, attention can seldom be absorbed fully in the review of historical events. It is not customary to proceed serially through the items of a history form. Even though the information is to be organized eventually in a formalized manner, the parents are encouraged to proceed spontaneously, and direct questioning is done later.

When the parents or the clinician seek clarification

of the nature of the difficulty the child is presenting or if information is needed about the abilities, psychological patterns, or physical state of the child, the procedures are diagnostic, and a more extensive historical exploration is undertaken.

Although the manner of eliciting the history is guided by the custom of the individual clinician and the spontaneous inclination of the informant, specified areas of inquiry must be covered to provide adequate background for the understanding of the child. Information is needed from the parents that the child cannot himself provide. After an exploration of the immediate concerns of the parents, a review of the child's current adjustment and history are pursued through a variety of dimensions. The information sought involves a family history and a developmental or past history of the child, with consideration of the development of the presenting problem.

As each incident has factual and emotional significance, the taking of a history could become a lengthy and involved process. It is necessary to develop a sense of what material may be of pertinence so that certain lines of investigation are explored more completely than others. The need to survey all the various indicated areas must be kept in mind, and some items may be noted and reserved for investigation at a later time.

The history is commonly pursued after the parents have been allowed to talk freely about the presenting difficulties and the child's current adjustment. When informants do not express themselves readily, it may be easier for them to respond to a methodical inquiry about the child's growth and development. The clinician can thus assist them to participate, having in mind that spontaneity can be allowed as the parents become more confident.

Areas of inquiry

Identifying data. Identifying data are obtained about each member of the immediate family and sometimes of the families of either parent. The data include names, sex, birth dates, occupation or school grade placement, race, religion, etc. Dates of marriages, divorces, and deaths are listed. The legal custody of the child and those who comprise his domestic setting are indicated.

Family history. The family history is a life or developmental history of each member of the family. The search for hereditary factors, chronic disease, and cultural influences leads the discussion to collaterals, grandparents, and other antecedents. More emphasis is placed on the emotional and social experiences of the parents and those who have been members of the immediate household. It is important to evaluate the solidity of the family and the quality of emotional nurture that has been provided. Through identifying data, the legal custody of the child has been indicated. Further inquiry may be necessary to ascertain whether ongoing responsibility in its full sense has been assumed for the child.

An evaluation of the maturity and social, behavioral, and emotional inclination of the parents is made with concern for the nature of the marital relationship and the emotional atmosphere of the home. Cultural and economic factors are considered. Special interest is directed toward the attitudes of the parents toward child rearing, discipline, direction, and supervision.

Indications of emotional disturbance in the life of either parent or conflict between parents are pursued. Special interest is directed to the manner in which the parents respond to the behavior of the child. It is sometimes possible to ascertain that the parent's insecurity, rejection, overprotection, indifference, etc., have played a primary determining role in the initiation of symptomatic responses in a child. In any event, whatever the parents' attitudes and feelings toward the behavior of the child, they are important to evaluate both from the point of view of understanding the nature and development of the difficulty and because the parents are going to be active participants in measures for treatment or management that be recommended.

Developmental history. A developmental history is the life history of the child. It provides information about his physical and psychological experiences. During the inquiry, attention is directed toward evaluating his motor competence, intellectual capacity, social responses, and emotional patterning. As age advances, social and interpersonal factors are increasingly complex, and the child's reactions are intertwined with the attitudes of those who care for him and with whom he associates.

Health history. In the health history, disease or biological influences that could affect the child through genetic potentiation or contagion are sought. Attention is directed to neuromuscular disorders, convulsive disorders, intellectual retardation, mental or behavioral abnormality, and chronic disease, such as tuberculosis. The circumstances of the pregnancy, birth, and neonatal period are reviewed for evidence of contagious disease, traumatic injury, and hematological or metabolic abnormality. Involvement of the central nervous system in febrile illnesses during infancy and early childhood may escape detection and become manifest later. The illnesses and injuries the child has experienced are discussed.

Motor skills and social reactions. A review of the acquisition of motor skills and social reactions yields information about the child's intellectual endowment and his emotional maturation. The final estimate of intelligence should be a clinical determination and is based, in good part, on historical information.

During the 1st year, before the development of speech, the rate of motor maturation corresponds closely to basic intellectual capacity, unless there is disease of the neuromuscular system. Inquiry is made into performances that parents commonly note. Among these are the time at which the child held his head erect, rolled over, sat up, cut his teeth, crawled, stood, walked, talked, etc. The progression of feeding patterns

from breast to bottle to spoon and the transition to solid foods, and self-feeding, control of bowel and bladder, sleep patterns, etc., are more complicated activities that are influenced readily through the relationship of the child and parent. As motor skills are acquired, the infant passes through a period of exploration of his physical surroundings and can play for limited periods by himself.

With greater social awareness, negativism to direction or insistence on independence develops. Between the ages of 4 and 5 years, the child should be able to play outside the home for periods of time and eventually to be away from his parents for considerable periods. Many children can attend kindergarten at 4 or 5 years, and most are expected to begin school by 6 years of age. Grade progression and subject achievement are important indicators of intellectual ability and/or emotional adjustment. Similarly, the development of social interests and the capacity to care for one's personal needs, to complete chores, and to participate in group play, become measures of maturity. With adolescence, social interest is heightened. Group and club activities must be more organized, and increased personal responsibility is expected. The patient's activities during vacation periods may be revealing. These include camp, organized recreation, and work.

An appraisal is made of the child's progress through the various developmental levels: prenatal and birth, infancy, 2 to 6 years, 6 to 12 years, and adolescence. Failure to acquire appropriate skills and interests may be due to intellectual or physical handicaps.

Symptoms. The patient may react to failure with symptoms, and parents may respond in a troubled manner, becoming overprotective, rejecting, etc. The development of symptoms and intrafamilial emotional pressures may precede the social or scholastic developmental lag and be of primary significance. Parental attitudes and the emotional and behavioral tendencies of the child are then the causal factors. This is the situation with primary emotional problems.

If maturation is not progressing normally, the child may present a variety of symptoms. Habits such as thumb sucking, scratching, hair pulling, head banging, masturbation, and clinging to favored objects are seen in the early years. Fears may be associated with refusal to carry out specific acts, to separate from parents, to attend school, etc. The child may present obsessive-compulsive phenomena. Some symptoms result from a reluctance to progress to a more mature level of behavior. These are exemplified in neglect of personal grooming, such as not tying shoe laces or buttoning buttons, not washing the face and hands or combing hair, carelessness with arrangement of clothes, etc. Immature behavior and a preference for childish toys, objects, and friends are also in this category. More complicated phenomena are the articulatory inaccuracies (such as baby talk), bed wetting, soiling, etc. Shyness, aloofness, aggressiveness, delinquency, and sexual misbehavior are examples of maladaptive

behavior with considerable social and psychological import.

Symptoms and symptomatic behavior are indications of emotional distress in the child, and they arouse expressions of concern by the parents. Such indications of difficulty may be traced through several levels of development, portraying patterned behavior that becomes characteristic for the child. Similarly, the responses of the parents may be followed, revealing the manner in which the parents deal with difficulties that obtrude in the family. This will facilitate an evaluation of the nature of discipline, encouragement and assistance, personal warmth and interest, etc., that each parent brings to the care of the child. Differences in parental aims or interests can be observed. These circumstances underlie the presenting problems that have motivated the parents to seek psychiatric help.

One notes whether the parent has attempted to deal with the difficulties as they have arisen and whether he has been ready or reluctant to seek professional advice. The age at which the patient is brought for psychiatric study may be significant, especially if the duration of the difficulty has been long. It is important to note whether the decision to find help was made by the parents out of their concern for the indications of emotional or social distress they observed or whether action was compelled by difficulties in which the child became involved outside the home. Trouble with school subjects or school attendance, difficulty with school friendships or group activities, etc., press parents, who have been worried about other indications of trouble for some time, to act. Parents of many delinquent adolescents who come before the juvenile court have been reluctant to acknowledge earlier evidences of distressed behavior.

Examination

The psychiatric examination of a child or adolescent consists of a consideration with him of the difficulties that have brought him to psychiatric attention. These are the expressed concerns of others for which he may or may not be prepared to accept responsibility. He has knowledge of the circumstances and events that have worried his parents, but he may have a limited understanding of them and of his feelings about them. There is a natural aversion to the intrusion into one's thoughts and feelings, but, in his early encounter with a psychiatrist, a child is expected to reveal them.

Preparation. Knowledge of the attitudes and feelings of another human being remain limited if that person does not participate actively in a motivated manner. The child who comes to an initial interview without prior knowledge of its purpose is usually perplexed, frightened, or angry. Even the youngest child who has acquired speech can understand that his parents are concerned and that he is to be the object of study or that change in him is required. This is a challenging circumstance but one in which he can respond purposefully.

Preparation should involve a simple and honest talk

with the child about what he is coming to the psychiatrist to accomplish. He should understand that the discussion will be about him and in relation to difficulties of which both he and the parents are aware. The difficulties are not new, and it would be unusual if they had not been repeatedly discussed within the family group. The element that is new is the decision to undertake action through psychiatric assistance.

The manner in which the parents prepare the child is important. If the parents have misgivings and are uncertain, the patient himself may be distrustful and uneasy. The parents have previously established acquaintance with the psychiatrist or the clinic. There has been consideration of their concerns during the historical review. A beginning worker is sometimes distressed to learn that, after a careful discussion with the parents of how they shall prepare a child, he comes for the examination with little understanding of what will transpire; he is either ill informed or misinformed. Experience teaches that much can be learned about the relationship of parents and child as they become actively involved together.

Technique. The psychiatrist endeavors to create an atmosphere in which the child can act and express himself and in which he, with his patient, can consider the difficulties that have brought them together. A simple direct approach with an implied respect for the feelings and concerns of the child avoids affectation and distrust. The patient naturally expects to discuss his troubles. Unless he plunges into them spontaneously, it is well to begin with less consequential material and to wait until he has shown some active initiative or inquisitiveness. The clinician should be ready to make the first overtures but also to be responsive if the child chooses to direct the discussion. It is natural to say something about the office or the play material that is in evidence or to confirm introductions. Questions about school, age, and the identification of other members in the family are familiar topics with a child. The conversation will shortly turn to the reasons for the child being in the interview. Prolonged delay in discussing meaningful material can establish a strained and defensive lethargy, just as too precipitous a beginning may arouse fear and a defensive attitude. It is well to establish, fairly early, the amount of time that will be spent together—number of interviews, their duration, etc.

It may be desirable to acknowledge the interest of the parents in what will transpire. A degree of confidentiality should be implied or acknowledged, but the child psychiatrist should avoid assurances that information will be withheld from the parents unless he intends to do so. Some child psychiatrists practice absolute confidentiality with a child or adolescent patient. Others recognize openly that events which concern the parents cannot be kept isolated and that patient and doctor must have a reasonable trust in each other.

One can anticipate that a child will be apprehensive

and uncertain as he finds himself in the presence of a professional person whom he has endowed with the power to influence his life. The way this initial fear is recognized and dealt with affects the nature of the relationship throughout the examination. Too abrupt and frank a confrontation may be terrifying, especially with the younger child. The adolescent who is challenged and chooses to deny his anxiety may remain passive; or, if he responds with hostility, he may find it hard to yield and be friendly eventually. The clinician will proceed sensitively, knowing that, as he becomes acquainted with his patient, the patient is also becoming acquainted with him.

Leaving the parents. A good deal can be learned from the way a child leaves his parents in the waiting room. Crises occur in which a fearful child or an uncertain overprotective parent cannot separate. If a child cannot leave his parent, it is sometimes helpful to have the parent accompany him to the interview room and leave as the child becomes familiar with the new surroundings. Some fearful children cannot leave their parents without parental encouragement, and this is not always available. Fortunately, whether through acquired skill or confidence, unmanageable separation problems are less frequent with the experienced clinician. Whatever the response, as the child leaves his parents to go to his separate interview, it is important that it be noted.

Play. Play is a natural mode of expression for a child. It is customary for the interview room to be equipped with a variety of familiar play materials that appeal at varying ages. Children are not comfortable in the usual office setting, where freedom of movement is not easily allowed. Even the older adolescent is usually more at ease in the informal atmosphere of a room with play equipment. The patient is aware of the communicative element in his actions and conversation. He does not become absorbed in play unless he is engaged in an especially meaningful constellation of thought. Sometimes children feign absorption in play to avoid meaningful discussion. If the child does play, in the literal sense of the word, the purposeful quality of the interview is diverted. It is, accordingly, best not to have too involved or attractive toys or too overwhelmingly varied a display.

The child's perceptions. In the diagnostic interviews, the clinician endeavors to learn how the child thinks and feels about himself. There is interest in his perception of the problems that have brought him to psychiatric attention. More important is his concept of himself as an individual, especially in relation to others. What is his estimate of his size, maturity, and competence? One wants to learn of his relationships within the family and the manner in which he perceives his parents, siblings, and others, including the feelings and attitudes each has toward the others. Interest is directed to his opinions about his social ability through discussion of friendships and participation in games, group activities, etc. The examiner

attempts to evaluate the intellectual level at which the child functions and to observe abnormalities in thought, action, and emotional responsiveness. An estimate is made of the child's ability to relate and communicate and of the level of responsibility he assumes for his behavior. The clinician hopes to be able to delineate habitual patterns of response that constitute the outstanding features of the personality.

The child's communications. The psychiatrist must learn to understand the language of the child. Methods of communication with the child or adolescent patient differ from those with the adult, who enters into discussion in a more orderly manner and who is more impelled by the social implications of the interview. A few characteristics of clinical communication with children can be illustrated.

Play materials. Children occasionally discuss their feelings and attitudes directly but more commonly utilize play materials in order to feel at home and comfortable. Significant statements may arise from apparently inconsequential play and are often couched in figurative language, as illustrated in the following situation.

A 5-year-old girl was playing with a family of dolls when she said, "I wish my daddy was here. He takes care of me. I can't write, and I have to go to school, but I won't like school." She looked thoughtfully at her fingernails and said, "These fingernails won't grow up." The psychiatrist commented, "I guess that somebody bites them." She continued, "Ellen bites them, and they won't grow up. But my daddy will grow them up. My father is missing me. He will wonder what I am doing up here. He is going to send me to school, and I hate it. I don't want to learn forever."

Toys. Toys may also be used as a vehicle for expression.

A 4-year-old girl, playing with a doll, said, "That's a baby girl. The baby is sleeping. After she's sleeping, she eats. She eats her breakfast, her lunch, and her dinner, and then she sleeps again. Honey wants to be locked in the bathroom. No, Honey is going to be locked in the dining room. Honey is the little girl doll. I'm awfully silly." The child had presented an eating problem, and, since she had introduced the topic, the psychiatrist asked why she had come to see him. She continued, "To get help about my eating. I came to get help from you." The psychiatrist replied, "I think if there's going to be any help, we're going to need your help too." She continued, "Well, I'll help you because, if I want to eat, I could. Someday I'll start to eat." She returned to her doll, "Now she's a very bad baby, . . ."

Action. Children tend to depict feeling in action. Even as a child experiences anxiety in a challenging situation, he attempts to find a way to handle it. The clinician learns to understand the child's expression of emotional feeling and to note the manner in which he responds.

An 8-year-old boy revealed his fear during the beginning of an interview and indicated the manner in which he tried to handle it by controlling the situation about him so that nothing would happen that would place more requirements on him.

As he came into the interview, he stated, "Don't call me Morton, call me John." He didn't like his name. He made people call him John. It was warm, and the psychiatrist opened a

window. The boy continued, "Don't open the window, it's too cold." He looked at the chairs and said, "Oh, if I sit on one of those chairs, I'll bust it. Yes, I'll bust it. I'll cave those chairs through once I sit on them." The psychiatrist said, "I imagine they're strong enough to hold you, but I suppose you feel a little frightened about using those chairs." The boy replied, "I have to sit down, but I'm not going to."

A 3-year-old girl was fearful and reluctant to participate but indicated readiness to become involved.

She cried, "Open that door, Mommy. Open that door, Mommy. I don't want to go up here." Reaching for a tray of toys, she found it too far away. The psychiatrist helped by pushing the toys toward her. She in turn pushed them away. This was repeated with a mechanical tank, and the psychiatrist said, "I guess you don't want me to help you." She continued crying but took the tank and tried to wind it, saying, "No, no. I don't want to play. I don't want to play." As she expressed her reluctance, she was handling the tank and trying to use it.

Painting and drawing. These are useful media for communication. With pencils, crayons, and paints, children are able to enter into expressive play that frequently has significance.

During World War II, a 10-year-old boy painted a picture of an airplane. He drew a swastika on the side of it and said, "I don't like Germany. I don't know why I make signs. Maybe I feel bad like the Germans do. Maybe I do." He decided to paint the whole page purple so that his mother would not know that there was anything on it. He continued, "I'll leave a little space so that my mother can look through, and she'll say, 'Germany.'" The examiner wondered if she would know what was in there. He replied, "Yes, it will be bad, but she won't know it. Here's where I'm going to put them." He left a large space at the top of the paper, in which he plainly drew a swastika. He turned and said, "She'll know that. Wow! I don't think she'll like this so good. I'm scared to take it downstairs."

The following is an expressive passage in which a 7-year-old boy was painting at an easel.

He decided to paint a house. As he was working, he said, "This house is haunted. Do people paint and draw houses every time they come here?" The psychiatrist supported his individuality and said, "No, they don't draw houses like yours. This is different because it is yours." The boy continued, "This house is haunted; it has spooks in it. You can't see the spooks. When you look in that house, you get scared. Oh yeah, you can't see in the windows. They're dirty, and when you go inside, the door creaks. It's almost too dangerous to look in." The psychiatrist said, "I guess, when you really feel like it, you will look in." The boy replied, "I'll carry a gun then." He painted over the doorway and wanted to know if the psychiatrist had even seen a house just like this. This time the psychiatrist replied, "No, I have never seen one just like it." The boy continued, "There's a witch in there. It's a candy house. There are only rich people." After a pause, "Something strange happened; the lady waved a wand." The psychiatrist replied, "Then it is different." The child continued, "Whoever goes in it is different. They don't come out, even if they are a hundred years old." The psychiatrist tried to point up what the child had been saying and asked if that was a little the way he felt inside, a little fearful? The child replied, "Who said I was? I am sometimes." The psychiatrist added, "And you worry about what's inside." The boy replied, "What's worry?" Then he answered his own question: "Thinking and fear. Why say it isn't?"

Correlation of Results

Through the direct examination, the psychiatrist brings clinical perspective into the several parameters

from which the child has been studied—historical, current, psychometric, and physical. The patient may allow an extensive acquaintance with his thoughts, emotions, and patterns of reaction, or he may restrict what can be learned about him. Even an examination with a responsive child, extended over several interviews, will leave some limitations in the knowledge that can be gained about him. When a child is reticent—whether because of timidity, incapacity, or antagonism—the direct observations cannot be extended to all the areas of thought and feeling that the examiner would wish to study in order to confirm his impressions. It is necessary then to place greater reliance on the history, psychological test results, and physical findings.

Diagnosis

Diagnosis in child psychiatry is a continuing process. Treatment and management involve the child with his parents. Further experience with the family and maturation in the child may be necessary to clarify diagnostic questions. The initial assumptions will be reassessed repeatedly as work with the family continues.

Suggested Cross References

Ancillary sources of data important in the psychiatric evolution of the child include psychological testing, social service information, and the neurological evaluation, which are discussed respectively in Sections 39.3, 39.4, and 39.2 in this chapter. See Area E, on assessment in psychiatry, for information about the psychiatric examination of adults.

TABLE I

Symptoms That May Be Manifestations of a Psychiatric or a Neurological Disorder

Most Common Age at Onset	Symptom	Diagnosis
yrs. 0-2	Recurrent episodes of crying and stiffness of body	Infantile functional colic or minor motor epilepsy
	Convulsions following holding of the breath	Breath-holding spells or epilepsy
2-6	Brief (momentary) episodes of inattentiveness and staring	Psychiatric disturbance or petit mal epilepsy
6-12	Somnambulism, night terrors, nightmares, and nocturnal laughing spells	Psychiatric sleep disorder or epilepsy
	Recurrent attacks of headache, abdominal pain, vomiting, and dizziness	Psychiatric disturbance or nonconvulsive epileptic equivalent
	Bizarre motor or psychic behavior	Psychiatric disorder or psychomotor epilepsy
12 through adolescence	Convulsions preceded by emotional upsets	Hysterical convulsion or major motor (grand mal) epilepsy
	Recurrent attacks of fainting	Psychiatric disturbance or epilepsy

stances the physical and neurological examinations give a clue to the diagnosis. When physical or neurological deficits are not detectable, the diagnosis may be made on the basis of the clinical history and the results of various laboratory procedures. This presentation is limited to the use of the clinical history and electroencephalography as diagnostic procedures in the evaluation of some of the symptoms that may be manifestations of a psychiatric or a neurological disorder (see Table I). For the purpose of this discussion, it is assumed that all other laboratory procedures appropriate for the case in question were nonrevealing.

39.2 NEUROLOGICAL EVALUATION IN CHILD PSYCHIATRY

SAMUEL LIVINGSTON, M.D.

LYDIA L. PAULI, M.D.

Psychiatric and neurological, especially epileptic, disorders may present similar symptoms. In some in-

Diagnostic Techniques

History. The importance of a comprehensive clinical history as a diagnostic tool cannot be overemphasized. Special attention should be directed to the age of onset and the prodromal features of the symptomatology, since these aspects frequently provide valuable diagnostic clues. For example, true petit mal epilepsy rarely, if ever, makes its onset during the first 2 years of life or after 15 years of age; and a

breath-holding convulsion is almost always preceded by an acute emotional upset and cry.

Electroencephalogram. In certain disorders, the electroencephalographic (EEG) examination reveals diagnostic abnormalities, such as the spike wave discharge of petit mal epilepsy and the hypsarrhythmic pattern of minor motor epilepsy. However, in other disorders, the electroencephalogram may show equivocal findings or may be normal. This is frequently the case in patients, particularly young children, who suffer with frank clinical evidence of major motor (grand mal) epilepsy.

Response to therapy. In those instances where the electroencephalographic examination is nonrevealing and the symptoms cannot be definitely classified on clinical grounds, one should make a tentative diagnosis initially and a final diagnosis in retrospect, depending on the response to drug therapy or psychotherapy. For example, in the case of a teen-ager who has recurrent major seizures in association with emotional upsets and a normal electroencephalogram, a definite diagnosis of hysterical convulsions or epilepsy cannot be made in many instances until one has had the opportunity to study the response to specific antiepileptic agents or psychotherapy.

Syndromes Requiring Differentiation between Psychiatric and Neurological Etiology

Recurrent episodes of crying and stiffness of the body. Young infants frequently present episodes of suddenly crying and holding themselves in a rigid position for a moment or so with their thighs drawn up toward their abdomen, appearing as if in pain. Sometimes there are fine trembling movements associated with the rigidity. In the absence of evidence of an organic central nervous system basis, these attacks are usually diagnosed as infantile colic. However, similar symptoms may be a manifestation of minor motor epilepsy (infantile spasms). The differentiation between these two disorders can usually be made on clinical grounds.

Minor motor epilepsy usually makes its initial appearance between 3 and 6 months of age. The spell of minor motor epilepsy varies somewhat in its clinical manifestations but most frequently consists of a sudden flexion or extension of the head with simultaneous extension of the arms and flexion of the thighs on the abdomen. It is frequently preceded or followed by a short cry, laugh, or giggle. The myoclonic feature, which is characteristic of the spell of minor motor epilepsy, is lacking in the clinical symptomatology of functional infantile colic. The spells of minor motor epilepsy almost always recur many times daily and frequently in series—10 to 15 spells in a row.

A definite differential diagnosis can be made with the use of the electroencephalogram. In minor motor epilepsy, the electroencephalogram reveals abnormalities almost always consisting of random high voltage spikes followed by large slow waves (hypsarrhythmia) as shown in Figure 1.

Convulsions following holding of the breath.

Breath-holding spells of the convulsive type can usually be easily differentiated on clinical grounds from epilepsy. The onset of breath-holding spells is usually during the first 2 years of life but rarely before 6 months of age. They tend to disappear spontaneously after 3 or 4 years of age and rarely recur after 6 years of age.

Breath-holding convulsions are almost always preceded by an obvious precipitating factor, such as a slight injury or some other provocative incident that creates an acute emotional upset in the child; in most instances, epileptic seizures occur spontaneously, without any apparent disturbing factor. Breath-holding episodes are preceded by crying and holding of the breath; young children with epilepsy rarely cry before an attack. Cyanosis appears with the crying and precedes the convulsions of breath-holding spells; in epilepsy the cyanosis usually appears after the onset of the convulsive movements. Opisthotonus almost always occurs in association with breath-holding spells; it rarely occurs with epileptic seizures. The electroencephalogram does not reveal specific abnormalities in patients with breath-holding convulsions.

Brief (momentary) episodes of inattentiveness and staring. A diagnosis of petit mal epilepsy should always be considered in a child who presents such disturbances as inattentiveness and staring episodes. It must be noted, however, that the most common age of onset of true petit mal epilepsy is between 4 and 8 years, and rarely much before 3 or after 15 years of age.

A diagnosis of petit mal epilepsy can almost always be established by carrying out the voluntary hyperventilation test and can be definitely established with the use of the electroencephalogram. A clinical spell can be precipitated in essentially all patients with petit mal epilepsy who are able to satisfactorily cooperate for the hyperventilation test. In most children, a clinical petit mal spell will appear after short periods, 1 to 2 minutes, of hyperventilation, but in

FIGURE 1. EEG of a 1-year-old child with minor motor epilepsy. This record was obtained during sleep artificially induced by secobarbital (Seconal). Note high voltage spikes followed by large slow waves (hypsarrhythmia).

FIGURE 2. EEG in petit mal epilepsy in an 8-year-old child. The record was obtained when he was awake. Note the classic 3 per second spike and wave discharge. The patient had a concomitant clinical spell.

other instances it may be necessary to hyperventilate the patient for 4 or 5 minutes in order to precipitate a spell.

The electroencephalographic abnormality of petit mal epilepsy is classic and consists of diffuse, bilaterally synchronous spike and wave forms that recur at frequencies varying from $2\frac{1}{2}$ to 4 per second but usually at 3 per second (see Figure 2).

Somnambulism, night terrors, nightmares, and nocturnal laughing spells. The differentiation of disturbances of sleep of epileptic origin from those of psychiatric origin is frequently very difficult on clinical grounds. The occurrence of electroencephalographic abnormalities concomitant with clinical symptoms during either natural or artificially induced sleep is definite proof of an epileptic disorder. The occurrence of electrical abnormalities during the awake state or during sleep unassociated with clinical symptoms should be considered as suggestive evidence of an epileptic disorder.

In those patients with normal electroencephalograms, the occurrence of diurnal symptoms of epilepsy suggests an epileptic basis for the sleep aberrations; the presence of marked emotional disturbances, such as fears and anxieties, favors a functional basis. In most instances, however, a definite diagnosis cannot be made except in retrospect, depending on response to specific antiepileptic drugs or psychotherapy.

Some patients present behavioral aberrations of various types during the postconvulsive stage of a major motor epileptic seizure. Therefore, if such a relationship between a sleep disturbance and a major seizure is established, the diagnosis is unquestionably that of epilepsy.

Recurrent attacks of headache, abdominal pain, vomiting, and dizziness. These are among the most common complaints the pediatrician is called on to interpret. Since these symptoms may be associated with many disorders, it is essential that all known causes be explored before a specific diagnosis is made. In some instances, a definite neurotic basis can be established, such as in the case of children with

school phobia or other anxieties and frustrations. In many patients, however, a definite basis for these symptoms cannot be elicited; for this reason, they are usually designated as functional in origin.

One should bear in mind that recurrent attacks of headache, abdominal pain, vomiting, and dizziness may be the only clinical manifestations of an epileptic disorder (nonconvulsive epileptic equivalent). A diagnosis of nonconvulsive epileptic equivalent—autonomic epilepsy, diencephalic epilepsy, thalamic-hypothalamic epilepsy—should be assigned to children who suffer with these symptoms and in whom the electroencephalogram reveals abnormalities like those seen in patients with overt epilepsy. In those patients with normal electroencephalograms, the following factors constitute evidence in favor of an epileptic disorder: (1) concomitant disturbance of the sensorium followed by stupor or sleep; or, (2) a beneficial response to specific antiepileptic medication.

An electroencephalographic discharge consisting of 6 per second and 14 per second positive spikes (see Figure 3) has been reported in many children with recurrent headaches, abdominal pain, and other symptoms suggestive of autonomic dysfunction. This pattern is also found in patients with other forms of epilepsy and in a significant number of "normal" children. The nature and significance of the 6 and 14 phenomenon remain controversial.

Within recent years, it has become apparent that migraine is much more prevalent in children than was previously thought. The classic unilateral headache is not commonly seen in children. Migraine headaches in children are almost always associated with gastrointestinal disturbances, such as nausea, vomiting, and abdominal pain. In fact, abdominal pain and vomiting are frequently the predominant symptoms of a migraine disorder in the younger child and in many instances precede the onset of the headache.

The diagnosis of migraine should be considered in those children who suffer with recurrent paroxysmal headaches associated with gastrointestinal disturbances. Unilateral headache, visual disturbances, or a history of migraine in the family are additional

FIGURE 3. EEG of a 9-year-old child with recurrent attacks of abdominal pain. The record was obtained during light sleep artificially induced by chloral hydrate. Note 6 per second and 14 per second positive spike discharge.

features that confirm the diagnosis. The electroencephalogram does not reveal abnormalities diagnostic of migraine; therefore, this examination cannot be used as a differential tool.

Bizarre motor or psychic behavior. Since a wide variety of behavioral aberrations—such as hallucinations, fugues, confused states, amnesia, temper tantrums, rages, and bizarre motor performances—may be manifestations of psychomotor (or temporal lobe) epilepsy, one is often faced with the difficult problem of differentiating psychomotor epileptic seizures from a psychiatric disorder.

Some clinical features that assist in differentiating a psychomotor seizure from a psychiatric aberration are: (1) Psychomotor epileptic seizures occur abruptly and spontaneously without any apparent precipitating factor; emotional aberrations are usually preceded by some disturbing situation. (2) There is usually complete amnesia for the psychomotor attack; in the emotional disorder, the individual usually has some recollection of the event and of the circumstances that precipitated the behavioral abnormality.

Behavioral abnormalities are sometimes seen during the postconvulsive phase of a frank major seizure. They may last for short periods of time or for hours. The evaluation of these behavioral aberrations, obviously, should not present a problem.

Electroencephalography serves as an important differential diagnostic tool, since most patients with psychomotor epilepsy present anterior temporal electrical irregularities, most commonly spikes (see Figure 4). This electroencephalographic abnormality is seldom seen in patients much under 6 years of age. In those patients with normal electroencephalograms, a diagnosis of psychomotor epilepsy, in many instances, cannot be made on clinical grounds except in retrospect, using the response to specific antiepileptic medications as one of the major criteria.

Convulsions preceded by emotional upsets. In most instances, the differentiation between a hysterical convulsion and a true epileptic seizure is not difficult on clinical grounds. Hysterical convulsions

FIGURE 4. EEG of a 12-year-old child with psychomotor (or temporal lobe) epilepsy. This record was obtained during natural sleep. It shows spikes localized to the right anterior temporal area.

are encountered most frequently in the older child. They are not usually associated with biting of the tongue, and generally there is no urinary or fecal incontinence. As a rule, the onset of the hysterical convulsion is less sudden than that of true epilepsy, and, in most instances, bodily injury from this spell does not occur. Postconvulsive sleep or stupor, which is commonly seen following a frank epileptic convulsion, is generally not observed after a hysterical convulsion; when it does occur, the patient can be aroused easily.

The interseizure electroencephalogram in most patients with frank epilepsy reveals specific electrical irregularities, such as spikes, random spike and wave forms, and abnormally slow waves; in patients with true hysteria it is normal. An electroencephalographic examination performed on a hysterical patient during an active convulsion and immediately thereafter reveals normal findings, whereas an electroencephalographic tracing recorded during a frank epileptic seizure reveals continuous spiking and abnormally slow high voltage waves during the postconvulsive phase.

One rarely has the opportunity to perform an electroencephalographic examination during an active seizure, especially on ambulatory patients. Therefore, in those patients with normal electroencephalographic

records in whom the clinical findings are equivocal, a definite diagnosis can be made in many instances only after the passage of time and favorable response to specific antiepileptic drugs and/or psychotherapy.

Recurrent attacks of fainting. Fainting (syncope) is an exceedingly common complaint, and relatively few people have not experienced this disturbance sometime during their lives. In most instances it is without major implications. When syncopal attacks occur repetitiously, a differential diagnosis frequently proves to be difficult. When disorders such as brain tumor, congenital heart disease, hypoglycemia, orthostatic hypotension, and carotid sinus sensitivity can be ruled out on the basis of physical, neurological, and laboratory examinations, the diagnosis almost always lies between a functional disturbance and some form of epilepsy.

Recurrent functional syncopal attacks of momentary duration must be differentiated from nonconvulsive epileptic equivalents. Functional syncopal attacks of longer duration frequently simulate atonic epileptic seizures. Some features that may assist in differentiating these two disorders are: (1) Functional syncopal attacks are almost always preceded by an exciting or disturbing situation, and the individual is generally aware of the waning of consciousness: in epilepsy, although there is some relationship between emotional upsets and the occurrence of seizures, the attacks generally occur abruptly and spontaneously. (2) The occurrence of electroencephalographic abnormalities of the type seen in patients with overt epilepsy constitutes evidence of an epileptic disorder.

In those patients with normal electroencephalograms, the differentiation between functional syncopal attacks and epilepsy frequently presents a diagnostic dilemma, and in many instances a definite diagnosis can only be made after the passage of time.

The "hyperventilation syndrome," which is thought to be functional in origin, may simulate an epileptic disorder in some of its clinical manifestations. This disturbance is occasionally seen in the teen-ager, but it occurs most commonly in older individuals, particularly nervous, anxious women who have other functional disturbances related to tension.

A narcoleptic attack may simulate an atonic epileptic seizure because of its paroxysmal and recurrent nature. Narcolepsy differs from epilepsy in the following respects: (1) The narcoleptic sleep is usually shallow, and the patient can be easily aroused; the patient cannot usually be aroused from the unconsciousness associated with the epileptic spell. (2) There is mental alertness following recovery from a narcoleptic attack; the atonic epileptic seizure is generally followed by a period of disorientation and drowsiness. (3) Narcolepsy is apt to respond to amphetamines; atonic epilepsy is more likely to respond to anticonvulsant medication.

Narcolepsy is sometimes associated with sudden loss of muscular tone and weakness, the cataplectic

attack. These attacks may simulate the akinetic or drop epileptic seizure in the brevity and general appearance of the spell. The cataplectic spell differs from the epileptic seizure in the following respects: (1) The cataplectic attack is almost always precipitated by some emotional disturbance; the akinetic or drop epileptic seizure generally occurs spontaneously. (2) Consciousness is maintained throughout the cataplectic attack; there is at least a momentary disturbance of consciousness associated with the epileptic seizure.

Most investigators have reported normal electroencephalographic findings in patients with narcolepsy. Within recent years several investigators have reported that the electroencephalograms of some narcoleptics show the occurrence of rapid eye movements (REM waves) at the onset of sleep.

Suggested Cross References

For information regarding the conduct of neurological examinations on children and adults see Area D, on neurology. Epilepsy is discussed further in Ervin's chapter (Chapter 21) in Area F, which deals with the psychiatric disorders of adults.

39.3 PSYCHOLOGICAL TESTING OF CHILDREN

ANNE ANASTASI, A.B. PH.D.

The principal focus of this section is on the evaluation of psychological tests and the interpretation of test results. Although the major types of ability and

personality tests currently available for use with children are described, no comprehensive survey of such instruments has been undertaken. Besides requiring far more space than is available, such a survey would be quickly outdated.

Because of the rapidity with which new tests are developed and revised editions of existing tests are prepared, the test user needs to be familiar with sources of information about tests. The most important of these is undoubtedly the series of *Mental Measurements Yearbooks* edited by Buros.¹ These yearbooks cover nearly all commercially available psychological, educational, and vocational tests published in English. While the coverage is especially complete for paper and pencil tests, major performance tests are also included. Each yearbook surveys tests published during a specified period, thus supplementing rather than replacing earlier yearbooks in the series. The *Sixth Mental Measurements Yearbook*, for example, includes tests published between 1959 and 1964. Beginning in 1938, the yearbooks have appeared at intervals of 2 to 6 years; understandably, these intervals have tended to lengthen as the volume of published tests has increased. Besides giving such routine information as price, length, general content, and age or other characteristics of persons for whom each test is designed, the yearbooks include critical reviews of the tests by one or more experts.

A comprehensive bibliography covering all published tests currently available in English-speaking countries is provided by *Tests in Print*, also edited by Buros. Information on recent tests, published in the years following the last available *Mental Measurements Yearbook*, can be found in several other sources. Short abstracts of new tests are regularly included in *Psychological Abstracts*. Reviews of current tests appear in a number of journals, such as the *Journal of Counseling Psychology* and the *Personnel and Guidance Journal*. For more detailed treatment of many of the problems discussed in this section, together with more extensive coverage of specific tests, the reader is referred to current textbooks on psychological testing, such as those by Anastasi and Cronbach. An excellent introduction to the use of tests in counseling and clinical practice is provided by Goldman.

Essential Technical Considerations in Test Evaluation

In evaluating the effectiveness and applicability of any psychological test, we need to ask certain basic questions regarding its reliability, validity, and norms. The information required to answer these questions should be provided in the test manual. When the necessary data are too extensive to fit conveniently into the manual itself, they may be presented in a technical supplement or published in other sources to

which references should be given in the manual. The present section provides an introduction to the principal concepts and techniques required for test evaluation and for the proper interpretation of test results. In this connection, reference is also made to the *Standards for Educational and Psychological Tests and Manuals*, a guide for test evaluation prepared and officially adopted by the American Psychological Association. First published in 1954, this guide was revised in 1966. It presents a summary of desirable practices in test construction, based upon the current state of knowledge in the field.

Reliability. Test reliability refers essentially to the consistency of scores obtained by the same individual on different occasions. Random fluctuations in test scores may result from several kinds of "chance errors" in test administration, scoring, condition of subject, or selection of items constituting a particular form of a test. Different methods for computing test reliability are influenced by one or more of these types of chance errors. Consequently, not all reliability coefficients have the same meaning. To interpret a reliability coefficient, it is necessary to know by what procedure it was found.

The principal procedures for computing test reliability include retest, equivalent form, split-half, and Kuder-Richardson techniques (for references, see Anastasi, 1961, Ch. 5). All these techniques report reliability in the form of a correlation coefficient between independently obtained measures. *Retest reliability* is the correlation between scores on the identical test administered at different times. The interval may vary from a few days to several months. Obviously this correlation shows degree of temporal stability from one test session to another. When parallel forms of a test are administered on the two occasions, the correlation between them represents *equivalent form reliability*. This measure is influenced by both temporal fluctuation and differences in subjects' responses to the two sets of items constituting the parallel forms.

The latter differences alone are measured by *split-half reliability*. The usual way to compute split-half reliability is to find each person's score on the odd-numbered items and on the even-numbered items. These two scores are then correlated and the reliability of the whole test estimated from this correlation of half tests. Like split-half reliability, *Kuder-Richardson reliability* is derived from a single test session. Being ultimately based on inter-item consistency, however, it is also influenced by homogeneity of test content. For example, in a test consisting of 50 vocabulary and 50 arithmetic items, the Kuder-Richardson reliability would be lower than in a test composed of 100 items of either type alone. Any discrepancy between subjects' performance on the verbal and numerical items would lower the Kuder-Richardson reliability of the first test.

Mention should also be made of *examiner* and *scorer reliability*. Most tests provide such highly

¹ All references cited by name are listed alphabetically at the end of this section. Tests are arranged in Table I, p. 1348, and alphabetized by title.

standardized procedures for administration and scoring as to leave little room for examiner variance. This is particularly true of group tests designed for mass administration and machine scoring. In most infant and preschool tests, however, as well as in other individual instruments for clinical testing, there is more opportunity for the examiner's judgment to operate. Under these conditions, some data on examiner reliability should be reported, in the form of a correlation between the results obtained by different examiners with the same subjects or through some other statistical index. Certain types of tests, such as projective personality tests, present special problems of scorer reliability. Whenever qualitative judgment is required in scoring, a sample of papers should be independently rescored by another examiner and the degree of agreement determined.

In interpreting the reliability coefficients reported in test manuals, certain precautions should be observed. The first relates to the subjects used in finding reliability. All correlation coefficients are affected by the range of scores or variability within the group. The greater the variability, the higher will be the correlation. Since tests are usually employed to differentiate among individuals within fairly narrow age levels, reliability coefficients should be reported separately for each level. This procedure also makes it possible to see whether the test is equally reliable at all ages. A single reliability coefficient found on a highly heterogeneous standardization sample, on the other hand, may be misleadingly high.

It should also be noted that reliability is directly related to test length. An abbreviated form of a test can thus be expected to show some loss in reliability. Similarly, subtests or parts of a test will have lower reliability than the complete test. If subtest scores are to be separately analyzed, as in a trait profile, reliability coefficients should be reported for each subtest.

With school-age children and older subjects, most well constructed tests of ability yield reliability coefficients clustering around .90. For infant and preschool tests, however, reliabilities tend to run lower. Among the conditions contributing to such low reliability are distractability, shyness, negativism, and other factors interfering with test administration. Reliability may be further lowered by scoring irregularities, since many test responses of the very young child consist of fleeting movements that leave no permanent record. Despite these difficulties, some of the more carefully developed infant tests, such as the Cattell Infant Intelligence Scale and the California First Year Mental Scale, yield split-half reliabilities between .70 and .95 after the first 3 months of age (for references, see Anastasi, 1961, Ch. 11).

Validity. The most important property of a test is undoubtedly its validity. The concept of validity concerns the relationships of a test to other data about the individual. An analysis of such relationships makes

it possible to state what the test measures and how well it does so. It is meaningless to report that a test is "valid" or possesses "high validity," without indicating the purpose for which it has the specified validity. For the selection of appropriate tests, as well as for the proper interpretation of test scores, full information is required regarding the procedures followed in estimating test validity.

In accordance with current usage, validity may be classified into three categories, namely, content validity, criterion-related validity, and construct validity. *Content validity* is most often used with educational achievement tests, although it also underlies the construction of certain personality inventories. This type of validity concerns primarily the adequacy with which the test items sample the content area to be measured. An achievement test, for example, may be checked against relevant course syllabi, textbooks, and the judgment of subject matter specialists. Coverage of essential topics, in the correct proportions, is the major consideration.

In *criterion-related validity*, test scores are correlated or otherwise compared with an outside criterion. The criterion is an independent index of those behavioral characteristics that the test is designed to measure. For example, a test of emotional instability may be validated by administering it to individuals known to have exhibited neurotic behavior, as well as to a normal control group. If the test differentiates significantly between the two groups, it is said to have concurrent validity for this criterion of emotional instability. Or an intelligence test may be administered to school children upon admittance to the first grade and their scores correlated with their educational achievement at the end of the school year. This correlation would represent the test's predictive validity against an academic criterion.

Construct validity is a very broad concept, covering a variety of validation procedures. It is concerned primarily with an experimental verification of hypotheses regarding the psychological traits or theoretical constructs that account for performance on the test. The most frequent application of this validation procedure is found in factorial validity. Thus if a factor of spatial visualization has been identified through factor analysis, the correlation of a test with this factor is its factorial validity. Essentially, this correlation indicates the extent to which the test measures an ability common to a group of similar tests which sample a relatively unified area of performance. Almost any experimental evidence regarding the correlates of test scores would contribute to construct validity. If, for example, a test is designed to detect anxiety, it could be administered to children before and after an anxiety-provoking experience (such as carrying out arithmetic computations under distracting and stressful circumstances). If the anxiety test scores rise significantly on the retest, the initial hypothesis regarding the test is confirmed. Still another

example of construct validation is provided by the age differentiation technique in terms of which most infant and preschool intelligence tests are validated. It is part of the construct of "intelligence" that this function improves with age in childhood. Therefore, individual test items, as well as total test scores, are checked against each child's age to see whether performance does in fact show progressive improvement with advancing age.

Norms. On any test, a "raw score," such as the number of items correct or the time required to complete a problem, is meaningless until compared with a norm or average performance. Psychological tests have no preestablished standards of passing or failing. Each new test must be administered to a large, representative sample of the population for which it is designed. The scores obtained by this group provide the test norms. Test manuals should always include such norms, together with information on the size and nature of the normative sample. The test user will then be able to evaluate the adequacy of the published norms and their applicability to the subjects he plans to test. Owing to differences in the characteristics of the samples upon which different tests have been standardized, the same individual may appear to perform much better on one test than on another, although both tests presumably measure the same trait. This is one of the reasons why test scores should always be accompanied by the name of the test with which they were obtained.

An individual's position in relation to the norms may be expressed in several ways. Basically, however, all such derived scores in current use fall into three categories: ratio I.Q.s, percentile ranks, and standard scores. The traditional intelligence quotient, or *ratio I.Q.*, is found by dividing a child's mental age by his chronological age. Theoretically, mental age represents the age of normal children whose test performance the child equals. Thus if a 10-year-old does as well on a test as the average 12-year-old, his mental age is 12, regardless of his chronological age. If, now, we divide his mental age ($M.A. = 12$) by his chronological age ($C.A. = 10$) and multiply by 100 to avoid decimals, we obtain an I.Q. of 120.

Despite its popular appeal, the traditional ratio I.Q. has serious technical deficiencies and has generally been replaced by more suitable measures. Few tests today have retained the ratio I.Q. Such I.Q.s can be properly employed only with age scales specifically constructed to yield comparable I.Q.s at different age levels. The essential requirement for such comparability is that the extent of individual differences, or variability, of I.Q.s shall remain constant at all ages. In statistical terms, this means that the standard deviation (σ) of the I.Q. distribution must be equal at all ages. This is a very difficult condition to impose upon the test constructor and has never been completely met in practice. When the condition is not met, an I.Q. of 115 at age 10, for example, might be equiva-

FIGURE 1. Varieties of test norms.

lent to an I.Q. of 140 at age 12, since both might fall at a distance of one standard deviation from the means of their respective age distributions.

A second major type of score is the *percentile rank*, which indicates the percentage of cases in the normative sample falling at or below the subject's score. Percentiles are not to be confused with the ordinary percentage score representing the percentage of items correctly completed. The percentile rank refers to persons, not items. Although satisfactory for crude evaluative purposes, percentiles do not provide a precise measure because of marked inequalities in size of units. Owing to the greater clustering of cases at the center of the range and the decrease in number of persons as the extremes are approached, percentile units near the center (i.e., 50) cover a much smaller distance than do those near the ends of the scale (i.e., 0 and 100). These size discrepancies can be seen by reference to the bottom scale of Figure 1. While percentile ranks correctly indicate the relative position of different individuals, they do not accurately reflect differences in amount of a trait.

The most precise measure is provided by *standard scores* and their various derivatives. In all such scores, the individual's distance from the mean is expressed in standard deviation units (σ). Thus if the normative sample has a mean of 38 and a standard deviation of 4, a raw score of 34 would correspond to a standard score of -1.00 . Such simple standard scores, utilizing the original σ of the distribution as their unit, are called *z scores* (see Figure 1). Several available derivatives of *z scores* provide more convenient scales, which avoid the use of negative numbers. An example is the *T score*, representing standard scores in a normal distribution with a mean of 50 and a σ of 10. As can be seen in Figure 1, a *T score* of 40 cor-

responds to a z score of -1.00 . Another type of standard score is the stanine, which utilizes a single-digit scale ranging from 1 to 9 and having a mean of 5 and a σ of 2. Because there are so few cases at the extremes of the distribution, stanines 9 and 1 represent larger units than the other stanines, extending from $+1.75\sigma$ to the upper end of the distribution and from -1.75σ to the lower end of the distribution, respectively (see Figure 1).

Of particular interest is the deviation I.Q., currently employed in the Wechsler Intelligence Scale for Children (WISC), the Stanford-Binet, and other recently developed intelligence scales. WISC deviation I.Q.s are actually standard scores with a mean of 100 and a σ of 15. Thus a child with a deviation I.Q. of 100 falls exactly at the mean of his age group. Deviation I.Q.s of 115 and 85 correspond to 1σ above and 1σ below the mean, respectively; a deviation I.Q. of 130 falls 2σ 's above the mean, and so forth. In the 1960 form of the Stanford-Binet, the earlier ratio I.Q. was replaced with a deviation I.Q. having a mean of 100 and a σ of 16. The latter value was chosen because it approximates most closely the standard deviations of the ratio I.Q.s found with the earlier forms of the Stanford-Binet and thus permits continuity of interpretation among forms.

Problems of Test Administration

Each type of test and each age level presents its own characteristic problems of test administration. The proper use and interpretation of most personality tests, for example, require extensive psychological training and experience. To qualify for the administration of individual intelligence tests such as the Stanford-Binet, as well as for any infant and preschool testing, the examiner needs an intensive course of specialized training. Practical suggestions for testing infants and preschool children are given by Goodenough (Ch. 20) and by Watson (Ch. 12). Terman and Merrill (pp. 46-58) discuss general procedures for the individual examination of older children.

Standardized procedure. Test scores are of little or no value unless obtained under uniform testing conditions. Failure on the part of inadequately trained examiners to realize the susceptibility of test performance to even slight variations in conditions is one of the chief causes of inaccurate test results. The need for uniformity applies not only to such obvious factors as time limits and wording of directions, but also to more subtle conditions. In certain tests, for example, performance may be appreciably affected by the rate at which the examiner speaks, where he places emphasis and when he pauses in his presentation, his facial expression while pronouncing key words that might reveal the correct answer, and the position of materials to be used by the subject. Any unusual condition of the subject, such as illness, fatigue, or excessive worry, may also affect test scores adversely. Even the nature of the subject's activities

immediately preceding a test must be taken into account. In two studies with the Goodenough Draw-a-Man Test of Intelligence, the mean scores obtained by school children were significantly higher after an emotionally gratifying experience than after a neutral or depressing activity (for references, see Anastasi, 1961, p. 63).

Emotional and motivational factors. Underlying the use of all ability tests is the assumption that the individual is "doing his best." Consequently, if conditions are to be kept uniform in this regard, every person should be motivated to put forth his maximum efforts on the test. Among the emotional and motivational conditions found to affect test performance are praise, reproof, ridicule, knowledge of results, presence of observers, competition and rivalry, and various conditions evoking feelings of frustration, failure, and discouragement. With preschool children, experience with adults outside the immediate family is likely to affect performance on individually administered intelligence tests. When a group of children were examined with the Stanford-Binet upon entering kindergarten and retested with a parallel form 2 months later, a significant mean rise in I.Q. was found (for references, see Anastasi, 1961, pp. 49-50). This gain was attributed largely to the effect of the kindergarten experience in reducing shyness, fear of strangers, and other attitudes inhibiting oral speech. Support for this hypothesis was found in the fact that the mean test-retest improvement was only 4.7% in manipulatory tasks, as contrasted with 11.2% in the oral items.

The nature and effects of "test anxiety" among school children have also been extensively investigated, particularly by Sarason and his associates at Yale. There is evidence that children vary widely and consistently in their susceptibility to anxiety while taking tests and that high degrees of anxiety have a deleterious effect on test performance.

It is likely that motivational factors in general are especially influential in the test performance of certain types of children, such as preschool children, emotionally maladjusted children, ethnic minorities, and members of lower socioeconomic classes. Juvenile delinquents, also, may approach tests with unfavorable attitudes, such as suspiciousness, insecurity, fear, or cynical indifference. Specific kinds of past experiences in the lives of some children may influence their test performance adversely. Because of early failure and frustration experienced in school work, for example, they may have developed feelings of hostility and inferiority toward any academic task, which most intelligence tests resemble.

Rapport and examiner variables. An important aspect of the examiner's function, particularly in the administration of individual clinical instruments, is the establishment of rapport. Essentially, this is a process for arousing interest and eliciting cooperation from the subject so that the objectives of the test will be most fully attained. In the case of an ability test,

good rapport means that the subject performs to his fullest capacity. On a self-report personality inventory, it means frank and accurate reporting of personal problems and difficulties rather than choosing answers to create a desired impression. Whether the latter tendency can ever be eliminated through proper rapport is doubtful; but it can at least be reduced.

The specific techniques for establishing rapport vary, not only with the objectives of the test, but also with the age and other characteristics of the subjects. In testing preschool children, for example, special factors to be considered include shyness with strangers, distractability, and negativism. A friendly, cheerful, and relaxed manner on the part of the examiner helps to reassure the child. The shy, timid child may need more time to become familiar with his surroundings before testing is begun. For this reason, it is better for the examiner not to be too demonstrative at the outset and to wait until the child is ready to make the first contact. At this age level, test sessions should be brief and the tasks should be varied and intrinsically interesting to the child. The testing should be presented as a game and the child's curiosity aroused before each new task is introduced. Some flexibility of procedure is necessary at these ages because of possible refusals, loss of interest, and other instances of negativism.

In the testing of children in the primary grades, the "game" appeal is still the most effective way of arousing interest in the test. The older school child, on the other hand, can usually be motivated by an appeal to his competitive spirit and his desire to do well on all kinds of tests. It should be kept in mind, however, that every test presents an implied threat to the individual's prestige. Some reassurance is therefore needed at the outset. The examiner should explain, for example, that no one is expected to finish or to get all items right. It should also be remembered that all these procedures for establishing rapport may need to be modified when testing children with special problems or backgrounds, as mentioned in the preceding section.

That test performance, particularly on individually administered intelligence tests and on projective tests, is significantly affected by examiner and situational variables is evidenced in a number of studies surveyed by Sarason (1954) and by Masling (1959, 1960). Among the significant examiner variables are age, sex, professional and social status, appearance, and such behavioral characteristics as self-confidence, aggressiveness, responsiveness, and social warmth. Situational variables are illustrated by the place where the test is given (school, clinic, hospital, prison, psychology laboratory), the expectations and attitudes established by the way the forthcoming test is presented to the subject, and the nature of specific instructions. The effect of all such conditions can be best conceptualized in terms of interaction between subject variables and examiner or situational variables. For example, such factors as ego-involving instructions and ex-

aminer's appearance have a different influence on subjects with different personality characteristics.

Practice, coaching, and test sophistication. It has been repeatedly demonstrated that scores on intelligence tests can be appreciably improved by practice and coaching (for references, see Anastasi, 1961, pp. 54-57). The effects differ widely, however, with the nature of the test and with the age, ability, and previous experience of the subjects. With certain tests, repetition of the identical form within a few weeks may make the retest score meaningless because of recall of previous responses by the subject. Even retesting with alternate forms generally produces some improvement over short time intervals. In such cases, some adjustment in score should be made to allow for practice effect. General test sophistication must also be considered in interpreting test performance. The child who has had extensive test-taking experience will usually score higher than the one who is taking his first test.

With regard to the effect of coaching upon test scores, a fundamental question pertains to the breadth of the resulting improvement. Is the improvement limited to the specific test items, or does it extend to the broader area of behavior that the test is designed to predict? The answer to this question represents the difference between coaching and education. Rote memorization of the correct responses to a list of vocabulary test items can markedly raise a child's score on that particular test without appreciably improving his general appreciation of word meanings. This would be coaching in the narrow sense and would reduce the predictive validity of the test for that child. On the other hand, a year of carefully selected reading, accompanied by a discussion of word meanings, would improve *both* the child's vocabulary test score and his general verbal comprehension, thereby leaving unaltered the test's validity.

Intelligence Tests

Testing the school child. It was for the school child that intelligence tests were first designed. In 1904, the French psychologist Alfred Binet was appointed to a commission to study the problem of retardation among Paris school children. Although for many years he had been exploring different approaches to the measurement of intelligence, it was to meet this practical demand that Binet, in collaboration with Simon, developed the first Binet-Simon Scale. Partly because they originated in an educational context and partly because they are commonly validated against academic criteria, intelligence tests measure primarily those abilities essential for academic achievement. For this reason, they are often more accurately described as tests of scholastic aptitude.

Typically, intelligence tests provide a global score, such as an I.Q., purported to indicate the individual's general intellectual level. They include a wide variety of tasks, on the assumption that through "the sinking of shafts at critical points" all important intellectual

TABLE I
Psychological Tests

The following table contains a list of all tests cited in this article. It is *not* to be construed as a comprehensive or recommended list; each test was mentioned only to illustrate a category. For a more complete coverage of available tests and for evaluations of each test, the reader should refer to current textbooks of psychological testing and especially to the *Mental Measurements Yearbooks* cited in the appended references section. It should be noted that the names of tests do not provide a reliable guide to the functions measured by the tests or the uses to which they may be put.

functions will be sampled. In actual practice, however, intelligence tests are overweighted with certain functions, usually verbal aptitudes, and may completely omit others.

The Binet-Simon tests were translated and adapted for use in many countries. In America, the most notable adaptation is the Stanford-Binet, developed by Terman and his associates at Stanford University. The latest revision of this test, published in 1960, is widely used as a clinical instrument. Extending from the 2-year level to three superior-adult levels of increasing difficulty, the test yields a mental age and a deviation I.Q. The standard materials employed in administering this test are pictured in Figure 2. Objects, pictures, and drawings are used largely at the younger ages; printed verbal and numerical materials occur increasingly at the older age levels. Oral questions and answers are common throughout the scale.

Another individual test commonly used in the clinical examination of children is the Wechsler Intelligence Scale for Children (WISC). This scale provides separate verbal and performance I.Q.s based on different sets of tests, as well as a full scale I.Q. Figure 3 shows a child taking one of the WISC performance tests, the object assembly test.

Both the Stanford-Binet and the WISC are individual tests, which must be administered to each subject singly and which require a highly trained examiner. They are essentially clinical instruments for the intensive study of individuals. In addition to the quantitative scores, such tests provide opportunities for observing work methods, social and emotional reactions, and other qualitative aspects of the child's behavior. Group tests, on the other hand, are designed for rapid mass testing. They not only enable a single examiner to test a large group during one session, but they are also relatively easy to administer and score. Group tests, of course, may also be administered individually. They are useful when a crude index of intellectual level suffices or when facilities for more intensive testing are unavailable. A number of well constructed and carefully standardized group tests have been developed for use from the first grade to college (for references, see Anastasi, 1961, Ch. 9).

Mention should also be made of nonlanguage and performance tests (for references, see Anastasi, 1961, Ch. 10). Comprising both individual and group tests, these instruments were designed especially for children with hearing, speech, or reading disabilities; the foreign-speaking; and the culturally disadvantaged. Other tests have been adapted for use with the blind or the orthopedically handicapped. Performance tests may also be employed as a supplement to such tests as the Stanford-Binet, in order to provide a fuller picture of the child's intelligence. The inclusion of performance tests in the WISC illustrates this approach.

Prechool and infant testing. Tests applicable prior to school entrance are conventionally subdivided into infant tests, designed for the first 18 months of

life, and preschool tests, covering the ages of 18 to 60 months (for references, see Anastasi, 1961, Ch. 11). The two levels require different procedures of test administration. The infant must be tested while lying

FIGURE 2. Test materials employed in administering the Stanford-Binet. (Courtesy Houghton Mifflin Co.)

FIGURE 3. Child taking the object assembly test of the Wechsler Intelligence Scale for Children. When properly assembled the pieces form a human figure. (Courtesy The Psychological Corporation.)

down or supported on someone's lap. Speech is of little or no use in giving test instructions, although the child's own speech development provides relevant data. Most of the tests at this level are actually controlled observations of sensorimotor development, as illustrated by the infant's ability to lift his head, turn over, reach for and grasp objects, or follow a moving object with his eyes. At the preschool level, on the other hand, the child can walk, sit at a table, use his hands in manipulating test objects, and communicate by language. At these ages, the child is also much more responsive to the examiner as a person, while for the infant the examiner serves chiefly as a means of providing stimulus objects. Preschool testing is a more highly interpersonal process, a fact that increases both its difficulties and its opportunities for observation.

One of the most extensive investigations of infant and preschool behavior is that initiated by Gesell at the Yale Clinic of Child Development. Following longitudinal studies of the normal course of development in the human child, Gesell and his associates prepared the Gesell Developmental Schedules (Gesell and Amatruda). These schedules are essentially a refinement and elaboration of the qualitative observations routinely made by pediatricians. Although a few may be properly described as tests, most of the items in the Gesell Schedules are based on observations of the child's everyday behavior. Data are obtained through direct observation of the child's responses to standard toys and other stimulus objects (see Figure 4) and are supplemented by information provided by the mother. The schedules yield separate scores indicating the level of the child's behavioral development, relative to the norms, in four areas: motor, adaptive,

language, and personal-social behavior. While extending from the age of 4 weeks to 6 years, the Gesell Schedules typify the approach usually followed in infant testing. Items from these schedules have been incorporated in several other scales designed for the infant level.

A more highly test-oriented approach is illustrated by the Cattell Infant Intelligence Scale. Extending from 2 to 30 months, this scale was developed as a downward extension of the Stanford-Binet and also includes some items from the Gesell Schedules. If a child passes any test at the 30-month level, testing is continued with the Stanford-Binet, beginning at the 3-year level. Between 22 and 30 months, Stanford-Binet items are intermingled with other items in the Cattell scale. A continuous scale is thus provided from the age of 2 months to the adult level.

A few scales have been developed for the preschool level only. In procedure and content, they have much in common with the lower levels of the Stanford-Binet and of performance tests (for references, see Anastasi, 1961, pp. 289-300).

Long term prediction. Theoretically, if a child maintains the same status relative to his age norms, his I.Q. should remain the same at all ages. Empirically, the I.Q. has in fact proved to be fairly constant for most children. In a follow-up of the Stanford-Binet standardization sample, for example, tests administered between the ages of 2 and 5½ years correlated .65 with retests after 10 years and .59 with retests after 25 years (Bradway, Thompson, and Cravens). Other longitudinal studies with preschool and school age children have yielded similar results (Bayley; Cattell; Honzik, Macfarlane, and Allen). On the other hand, scores on infant tests, obtained

FIGURE 4. Test objects employed with the Gesell Developmental Schedules. (Courtesy The Psychological Corporation)

prior to the age of 18 months, are virtually useless in predicting intellectual level in late childhood. The correlations between these tests and I.Q.s during school ages are usually zero or low negative (Bayley). In their present form, infant tests find their chief usefulness in the early detection of severe retardation resulting from organic causes of either hereditary or environmental origin. Among the reasons for the negligible correlations between infant tests and later intellectual performance is the heavy reliance of infant tests on sensorimotor functions. These functions bear little relation to the verbal and other abstract functions that comprise intelligence in later years.

Even in later childhood, however, the I.Q. cannot be regarded as rigidly fixed. A major reason for the usual stability of the I.Q. is that most children remain in the same type of environment throughout their development. Another is that their previous experiences determine their level of attainment in prerequisite intellectual skills needed for subsequent learning. An early deficiency thus becomes cumulative unless corrected by special remedial programs.

Longitudinal studies have demonstrated that in individual cases large upward or downward shifts in I.Q. may occur, depending upon the child's subsequent experiences. In one extensive follow-up project, individual I.Q. changes of as much as 50 points were found (Honzik, Macfarlane, and Allen). Between the ages of 6 and 18 years, when retest correlations are usually high, 59 per cent of the cases changed 15 or more I.Q. points, 37 per cent changed 20 or more points, and 9 per cent changed 30 or more points. These changes were not random or erratic, but exhibited consistent upward or downward trends over several years. Large shifts in I.Q., moreover, were usually associated with cultural milieu and emotional climate of the home. Children in disadvantaged environments tended to lose with age, while those in superior environments tended to gain, in relation to test norms. Changes in I.Q. have also been found to be related to certain personality characteristics of the child, such as emotional independence and achievement motivation (Sonntag, Baker, and Nelson).

Aptitude Tests

Shortly after the first intelligence tests came into general use, their limited coverage became apparent and efforts were made to construct tests of special aptitudes to fill the gaps (for references, see Anastasi, 1961, Chs. 14 and 15). Since most intelligence tests concentrate on the more abstract verbal and numerical abilities, a particular need was felt for tests measuring the more concrete and "practical" intellectual skills. Accordingly, mechanical aptitudes were among the first for which special tests were developed. Tests of clerical aptitude, measuring chiefly perceptual speed and accuracy, and tests of musical and artistic aptitudes followed. Many of these tests are particularly useful in vocational counseling.

Following the application of factor analysis to research on the composition of intelligence, it was recognized that intelligence tests themselves cover a limited number of relatively independent aptitudes. As a result of these findings, many recently developed intelligence tests report separate scores on verbal and numerical abilities, either in place of a total composite score or in addition to it. Another related finding is that different intelligence tests may measure different combinations of abilities. Nonlanguage and performance tests, for example, are often heavily loaded with spatial and perceptual abilities; some intelligence tests are almost entirely measures of verbal comprehension; still others combine verbal and numerical functions. Even a single scale, such as the Stanford-Binet, may measure different functions at different age levels (for references, see Anastasi, 1961, pp. 204-205). The diversity of functions measured by different intelligence tests provides one of the reasons for insisting that every test score be accompanied by the name of the test from which it was derived. An unlabeled "I.Q." may be quite misleading.

The most direct effect of factor analysis upon psychological testing has been the development of multiple aptitude batteries. Rather than yielding a single global score, such as an I.Q., these batteries provide a profile of scores on separate tests, most of which correspond more or less closely to traits identified through factor analysis. Several batteries of this type are now commercially available (for references, see Anastasi, 1961, Ch. 13). An example is the Differential Aptitude Tests (DAT), for which the largest amount of validity information has so far been gathered. The DAT yields scores in eight abilities: verbal reasoning, numerical ability, abstract reasoning, clerical speed and accuracy, mechanical reasoning, space relations, spelling, and grammar. In Figure 5 is a profile chart showing the DAT scores of a junior high school boy whose greatest strengths are in verbal reasoning and numerical ability. The score in the third column, based on the sum of these two scores, gives a single index of scholastic aptitude similar to that obtained from most intelligence tests.

Factorial analyses conducted at different ages suggest that intelligence may be relatively undifferentiated in early childhood, becoming increasingly specialized with age. Consequently, multiple aptitude batteries are most useful in the testing of older children and adolescents. One of their chief applications has been in educational and vocational counseling.

Educational Tests

Although nearly every type of test is used in schools, certain tests have been specially developed for educational purposes. Of particular interest are tests of readiness, tests of special educational disabilities, and educational achievement batteries (for references, see Anastasi, 1961, Chs. 16 and 17; Cronbach, Ch. 13).

Readiness tests. Readiness tests are designed to as-

FIGURE 5. Profile of scores on the Differential Aptitude Tests. Vertical bars show distance above or below norm on each test. Percentiles are spaced to correspond to equal distances in a normal distribution. (Reproduced by permission Copyright 1963, The Psychological Corporation.)

sess the child's specific qualifications for school work. Essentially "readiness" refers to the development of prerequisite skills and knowledge that enable the learner to profit maximally from a certain kind of instruction. Individual differences in the reading readiness of 1st grade school children provide a familiar example. At one time, readiness was considered largely in terms of maturation. To be sure, the attainment of certain minimum physical prerequisites facilitates some kinds of learning. Unless he can make the necessary auditory discriminations, the child cannot learn to speak by the usual procedures; without the ability for fine motor coordination, he cannot manipulate a pencil in writing. Most school learning, however, is not so closely related to sensorimotor development. In the mastery of educational tasks, the importance of prior learning is being increasingly recognized. More and more emphasis is being placed upon the hierarchical development of knowledges and skills, whereby the acquisition of simpler concepts equips the child for the learning of more complex concepts at any age.

Readiness tests are often administered upon school

entrance. At this level, they have much in common with intelligence tests for children in the primary grades. In the readiness tests, however, special emphasis is placed upon those abilities found to be most important in learning to read; some attention is also given to the prerequisites of numerical thinking and to the sensorimotor control required in learning to write. Among the specific functions covered are visual and auditory discrimination, motor control, verbal comprehension, vocabulary, quantitative concepts, and general information. A well known example is the Metropolitan Readiness Tests. Comprising six subtests, this test yields a total readiness score for 1st grade work.

Tests of special educational disabilities. At all educational levels, tests are available to aid in the diagnosis and remedial training of children with special educational disabilities, principally in reading and arithmetic. Since the treatment of reading disabilities is of special interest to psychologists, reading tests are probably more often used in clinical examinations than any other type of educational test. Reading tests are customarily classified as survey and diag-

nostic tests. Survey tests indicate the general level of the child's achievement in reading. They usually provide a single score, although some differentiate between speed of reading and comprehension. These tests serve largely to screen children in need of remedial instruction.

Diagnostic tests are designed to analyze the child's performance and identify specific sources of difficulty. Although all such tests yield more than one score, they range from group tests providing little more information than a survey test to intensive clinical programs for individual case studies. Some include detailed checklists of specific types of errors. The individual batteries frequently employ apparatus, such as tachistoscopes for controlling rate of exposure of printed matter and ophthalmographs for photographing the child's eye movements while he reads. In dealing with reading disabilities, information about possible emotional difficulties and a complete case history are also essential.

Educational achievement batteries. Of all tests used in schools, the most numerous are undoubtedly achievement tests, the principal aim of which is to measure the effects of a course of study. Some are comprehensive achievement batteries, designed to assess the pupil's over-all progress in school work; others test for mastery of specific subjects or courses. In keeping with modern curricular trends, many achievement tests today measure the attainment of relatively broad educational goals cutting across different subject matter specialties.

An outstanding example is the Sequential Tests of Educational Progress (STEP). These tests are available at several levels extending from the 4th grade of elementary school to the sophomore year of college. At each level, there are seven tests, including multiple choice tests in reading, writing, mathematics, science, social studies, and listening, as well as an essay writing test. Although the need for specific knowledge in particular fields was recognized in constructing STEP items, major emphasis was placed upon the application of learned skills to the solution of new problems.

Achievement tests have traditionally been contrasted with intelligence tests. From one angle, the difference between them stems from the degree of uniformity of relevant antecedent learning. Achievement tests measure the effects of relatively standardized sets of experiences, such as a course in 4th grade arithmetic or American history. By contrast, intelligence test performance reflects the cumulative influence of a multiplicity of experiences of daily life. Thus, achievement tests may be said to measure the effects of learning under partially known and controlled conditions, whereas intelligence tests measure the effects of learning under relatively uncontrolled and unknown conditions.

In this connection we should guard against the erroneous assumption that achievement tests are concerned with the effects of learning, while intelligence

tests tap "innate capacities" independently of learning. Although this misconception was prevalent in the early days of psychological testing, it is now recognized that all tests measure current developed abilities, which inevitably reflect the influence of prior learning. It should also be added that several recently developed achievement tests cover relatively broad and unstandardized educational experiences, thus overlapping traditional achievement and intelligence tests. A particularly good example is provided by the previously cited STEP. Stressing broad intellectual skills, STEP resembles intelligence tests more closely than it does the older type of achievement tests with their emphasis on recall of specific factual content.

Creativity Tests

The growing recognition that creative talent is not synonymous with academic intelligence, as measured by traditional intelligence tests, has been accompanied by vigorous efforts to develop specialized tests of creativity. An extensive investigation by Guilford and his associates, utilizing the techniques of factor analysis, has produced a variety of new types of tests as well as a theoretical schema for integrating creative functions into a broadened conception of intelligence.

Several tests designed in the Guilford project have been adapted for use with children. The research of Getzels and Jackson with high school students and of Torrance with younger children has utilized such creativity tests, and has provided suggestive data on the concomitants of creative achievement in childhood. The tests involve principally various aspects of fluency, flexibility, and originality, which Guilford subsumes under the heading of "divergent thinking." Described as "the kind of thinking that goes off in different directions," divergent thinking is contrasted with convergent thinking, which leads to a single right answer determined by the given facts.

An example of a test that is effective with young children is the "Improvements" test, in which the child is given toys, such as nurse kit, fire truck, and dog, and is asked to think of ways for changing each toy so it would be "more fun to play with." Thinking up unusual uses for common objects, such as a tin can, a brick, or a paper clip, illustrates another technique that has proved applicable over a wide age range.

Personality Tests

Although the number of available personality tests is large and their techniques varied and often ingenious, most of these tests must still be regarded as experimental instruments (for references, see Anastasi, 1961, Chs. 18-21). In comparison with tests of ability, personality tests, on the whole, are much less satisfactory with regard to such technical properties as norms, reliability, and validity. For these reasons, any information obtained from personality tests should be verified and supplemented from other

sources, such as interviews with the child and his associates, direct observations of behavior in natural situations, and case history material.

The personality tests employed most widely in examining children are of two major types: self-report inventories and projective techniques. In addition, a wide variety of other procedures has been devised, such as situational tests, objective laboratory-type tests, measures of self concepts, and techniques for exploring personal constructs (for references, see Anastasi, 1961, Ch. 21). In their present state of development, however, these instruments are suitable chiefly for research purposes, rather than for routine operational use.

Self-report inventories. Self-report inventories originated in an attempt to standardize the psychiatric interview and to provide norms for evaluating the individual's responses. Essentially they consist of a series of questions which the individual answers about himself, concerning emotional problems, worries, and other deviant behavior. The technique was later extended to the investigation of individual differences in other, nonpathological traits, such as interests, motives, values, and interpersonal traits.

Several inventories designed for children and adolescents are basically checklists of personal problems constructed on the principle of content validation. In other words, the questions pertain directly to the information the examiner wishes to elicit about the child's feelings and actions. The responses are thus taken at face value as an indication of the behavior to which they refer. A clear example of this approach is the Mooney Problem Check List. Designed chiefly to identify problems for group discussion or for individual counseling, this checklist drew its items from written statements of problems submitted by about four thousand high school students, as well as from case records, counseling interviews, and similar sources. The checklist is available in junior high school, high school, college, and adult levels. The problem areas covered in the junior high school form include: health and physical development; school, home, and family; money, work, and the future; boy and girl relations; relations to people in general; and self-centered concerns. Other examples of this type of inventory include the SRA Junior Inventory, for grades 4 to 8; the SRA Youth Inventory, for grades 9 to 12; and the California Test of Personality, available in five levels extending from kindergarten to college. Several inventories for the detection of anxiety in children are also available (see, e.g., Sarason et al.).

A somewhat different approach is illustrated by the IPAT Children's Personality Questionnaire and the Jr.-Sr. High School Personality Questionnaire. Utilizing items selected by factor analysis, these inventories yield scores in a number of different personality traits. In general, questions are used in these inventories, not as a means of eliciting specific information,

but as verbal stimuli the responses to which are scored in terms of their empirical correlates. Each item retained in the questionnaire serves as an indicator of a cluster of interrelated behavior tendencies. While the basic methodology is promising, the two questionnaires actually developed are limited in their usefulness by the low reliability of several trait scores and by insufficient validity data. In conclusion, personality inventories today find their major usefulness in screening and identifying children in need of further investigation.

Projective techniques. The chief characteristic of projective techniques is that the subject is assigned an unstructured task, which permits an almost unlimited variety of possible responses. The test stimuli are typically vague and equivocal, and the instructions are brief and general. These techniques are based on the hypothesis that the way the individual perceives and interprets the test materials, or "structures" the situation, reflects basic characteristics of his personality. The test stimuli thus serve as a sort of screen on which the subject "projects" his own ideas.

One of the most widely used projective techniques is the Rorschach, in which the subject is shown a set of bilaterally symmetrical inkblots and asked to tell what he sees, or what the blot could represent. Although for many years the Rorschach was used principally with adults, Ames and her co-workers (1952 and 1959) at the Yale Institute of Child Development have published Rorschach norms for children between the ages of 2 and 10 years, and for adolescents between the ages of 10 and 17. The availability of these norms puts the interpretation of child Rorschach responses on a sounder and more objective basis.

A somewhat more structured test is the Children's Apperception Test (CAT). This test is an adaptation of the Thematic Apperception Test (TAT), developed by Murray. In the CAT, however, pictures of animals are substituted for pictures of people, on the assumption that children respond more readily to animal characters. The animals are portrayed in typically human situations, in the anthropomorphic style common in children's storybooks. The pictures are designed to evoke fantasies relating to problems of feeding and other oral activity, sibling rivalry, parent-child relations, aggression, toilet training, and other childhood experiences. Another example is the Blacky Pictures, a set of cartoons showing a small dog, his parents, and a sibling (see Figure 6). Based on a psychoanalytic theory of psychosexual development, the cartoons depict situations suggesting various types of sexual conflicts. Still another type of picture test is illustrated by the Rosenzweig Picture-Frustration Study. Derived from the author's theory of frustration and aggression, this test presents a series of cartoons in which one person frustrates another. One of these cartoons, from the children's form, is shown in Figure

7. In the blank space provided, the child writes what the frustrated person would reply.

Drawings, toy tests, and other play techniques represent another application of projective methods. Because children are more limited than adults in their facility for verbal communication, these nonverbal procedures are commonly used in the examination of children. Although almost every art medium, technique, and type of subject matter has been investigated in the search for significant diagnostic clues, special attention has centered on drawings of the human figure. Play and dramatic objects, such as puppets, dolls, toys, and miniatures, have also been widely utilized in projective examinations. The objects are usually selected because of their associative value, often including dolls representing adults and children, bathroom and kitchen fixtures, and other household furnishings. Play with such articles is expected to reveal the child's attitudes toward his family, as well as sibling rivalries, fears, aggressions, conflicts, and the like.

When evaluated as standardized tests, most projective techniques have fared quite poorly. In their present state of development, these techniques should be regarded not as tests but as aids to the clinical interviewer. They can serve a useful function, particularly with children, in evoking communication regarding emotional problems whose discussion the individual might otherwise eschew for a variety of reasons. The effectiveness of any one projective technique, however, cannot be evaluated independently of the skill of the clinician using it.

Cultural Differentials in Test Performance

In the measurement of both abilities and personality traits, tests yield significant mean differences between children reared in different cultures or subcultures, such as socioeconomic levels, urban and rural environments, and minority groups (for references, see Anastasi, 1958, Chs. 15-17). For this reason, several attempts have been made to develop so-called "culture-free" or "culture-fair" tests. The earliest culture-free tests were designed on the premise that hereditary intellectual potential could be measured independently of the impact of cultural experiences. The individual's behavior was thought to be overlaid with a sort of cultural veneer, whose penetration became the goal of culture-free testing.

It is now generally recognized, however, that hereditary and environmental factors interact at all stages in the organism's development and that their effects are inextricably intertwined in the resulting behavior. For man, culture permeates nearly all environmental contacts and thus affects all behavior development. Since psychological tests are essentially samples of behavior, cultural influences will, and should, be reflected in test performance. It is therefore futile to try to devise tests that are *free* from cultural influ-

FIGURE 6. Sample item from the Blacky Pictures. (Reproduced by permission of Psychodynamic Instruments, Ann Arbor, Michigan.)

FIGURE 7. Sample item from Rosenzweig Picture-Frustration Study, Form for Children. (Reproduced by permission of Saul Rosenzweig.)

ences. The present objective of cross-cultural testing is, rather, to construct tests that presuppose only experiences *common* to different cultures. Available culture-fair tests eliminate one or more parameters along which specific cultures differ, such as language, reading, speed, or culturally loaded content.

No existing test is universally applicable or equally fair to all cultures. Although less restricted than other tests, culture-fair tests are never completely unrestricted in their cultural reference. Any test tends to favor individuals from the culture in which it was developed. The mere use of paper and pencil or the presentation of abstract tasks having no immediate practical significance will favor some cultural groups and handicap others. Cultural differences in emotional and motivational factors may also influence test performance. Examples include intrinsic interest of test con-

tent for the individual, rapport with the examiner (who may be a member of another culture), drive to do well on tests, desire to excel others, and past habits of solving problems individually or cooperatively.

A fundamental question pertains to the validity of culture-fair tests. Whatever the purpose of testing, one should be able to generalize beyond the test itself. Tests are administered so that conclusions may be drawn about what the individual will do in other situations. Therefore, whether the elimination of cultural differentials from a test will raise or lower its validity for any group depends upon the breadth of the cultural differentials. For example, if a test item requires the interpretation of a proverb familiar to children in one culture but not in another, its inclusion would probably lower the validity of this test against most criteria. On the other hand, if one group performs more poorly than another on certain items because of inadequate linguistic facility, the inclusion of these items would not reduce validity of the test for most purposes. In this case, the same condition that lowered the test score would also handicap the child in his educational progress and other activities of daily life. Similarly, slow work habits, emotional insecurity, low achievement drive, lack of interest in abstract problems, and many other culturally linked conditions affecting test scores are also likely to influence broad areas of criterion behavior.

In the testing of children from varied cultural backgrounds, no universal culture-fair test is suitable. Culture fairness in testing depends upon the elimination of relevant cultural parameters. A nonlanguage test may reduce cultural handicap for children from one culture, but increase it for children from another culture. Available culture-fair tests, moreover, differ among themselves in the extent to which they measure different abilities. When spatial content is substituted for verbal content, for example, the nature of the abilities sampled by the test may thereby be altered drastically. While an I.Q. on one such test may be largely a measure of abstract reasoning, on another it may depend chiefly on spatial and perceptual abilities. Finally, whether or not cultural differentials should be eliminated from a test depends upon the effect their elimination will have on the test's validity for specific purposes. Cultural handicaps tend to be self-perpetuating and cumulative, unless eliminated by special remedial programs. That they can be overcome has been widely demonstrated by the many compensatory educational programs for culturally disadvantaged children initiated in America during the 1960's (for references, see Bloom et al.); but the use of tests that fail to detect the handicap is no solution.

Suggested Cross References

For further information regarding psychological testing see Sections 12.1 and 12.2, which deal respectively with tests of intelligence and personality in adults and with tests for organic brain damage in

adults and children. Information regarding fundamental concepts of perception and cognition which underlie the construction of some of the psychological tests that were mentioned in this section may be found in Sections 3.1 and 3.2 in Area B, on the basic behavioral sciences.

39.4 SOCIAL SERVICE INFORMATION IN CHILD PSYCHIATRY

MAURICE R. FRIEND, M.D.

Since child psychiatry considers both intrapsychic and interpersonal deviations, any assessment entails consideration of the social behavior of the child in the context of his family, school, and other groups. A child does not communicate and view himself as an adult does, and so the psychiatrist must have the family and school viewpoints of the child's behavior before completing the diagnosis and planning treatment. The child, with few exceptions, does not voluntarily participate in treatment without the support and wish of his parents or without social pressures.

Social work is particularly geared to identify current situational tensions or supportive relationships by obtaining historical and current social facts. Social work in a psychiatric hospital, in-patient or out-patient service, or child guidance clinic involves individual casework and group work. When this takes place in a psychiatric setting, the social work is termed "psychiatric social work."

Use of Social Work

Traditional use of psychiatric social work involved direct interview of the child by the psychiatrist and family interview by the social worker. This has proved to be limiting in scope, and many flexible variations have arisen, depending on the particular setting in which assessment and treatment of the child are provided.

Social work may be used to prepare family and child for the nature of the services provided—the diagnostic procedures used and the means of treatment once goals have been established. Observational home, school, and neighborhood visits may be of great assistance in the evaluation of certain stressful situations that are not perceived by the parents. Social work may add considerably to the therapist's understanding of a family's deviations from prevailing current behavior in various social classes.

Emotionally and socially, children rarely grow in a straight line. Regression as well as progression is to be expected. Generally, children's problems reflect the various aspects of their family figures and the parental unconscious conflicts and ideals. Social workers can, by virtue of their training, assess family interactions that may aggravate and perpetuate emotional problems.

In those instances where there are behavioral disturbances at home but not outside the family, the psychiatric social worker can help assess infantile, neurotic conflicts. Diffuse aggressive behavior with low frustration tolerance both at home and in school points to obvious social displacements of early reactive situations.

Since children are inseparable from their family setting and psychological representations of significant family figures and since assessment and diagnosis is never concluded until maturity is biologically possible, the psychiatric social worker can contribute greatly to the continuity of care and follow-ups of the initial diagnostic work-up. The social worker can contribute to the continued exploration of the efficacy of the treatment process.

Preparation of a social history must evolve from a therapeutic relationship with either the child or the family. The social worker can secure pertinent material for understanding the family, enlisting the help of people important to the patient, and preparing them for his treatment and what it means to them.

Chapter 40

Psychiatric Disorders of Childhood. I: Healthy Responses, Reactive Disorders, and Developmental Deviations

40.1 **HEALTHY RESPONSES, DEVELOPMENTAL DISTURBANCES, AND STRESS OR REACTIVE DISORDERS. I: INFANCY AND CHILDHOOD**

STELLA CHESS, M.D.

Developmental Disturbances

Disturbances in behavioral development in the young may involve either (1) over-all developmental retardation, (2) retardation in one function or a small group of related functions, or (3) uneven development, in which precocious development in one area goes along with normal development in others. A further consideration involves the determination as to whether a developmental deviance represents an organic defect or a temporary lag. The organic defects as a group may be characterized by definable and static impairment of function, or they may represent either a deteriorating situation or one in which there will be partial amelioration. The developmental lags, on the other hand, are characterized by a spurt of development with eventual near normal, normal, or even superior level.

The neurological conditions of childhood are important sources of disturbances in behavioral development. These, however, have been discussed elsewhere and will not be repeated here. Of the developmental lags, the most frequently found are retardations in language development, in coordination, and in perceptual organization. Since defects in all these areas are characteristically found in mental retardation, it is of great importance in differential diagnosis and in planning therapeutic procedures to differentiate between a permanent defect and a temporary lag.

Language lags, for example, may be the first sign of mental retardation. History and examination will make it possible to compare the child's verbal level with his cognitive capacities as demonstrated by his nonverbal activities: response to nonverbal signals, the manner in which he accomplishes routines, his level of interpersonal activity, his choice and level of play. If his nonlinguistic behavior is uniformly at age expectancy and only language is retarded, one may determine that this is a specific language defect. Whether this is a permanent defect in the aphasic category or a temporary defect may not be possible to decide without obtaining a longitudinal picture of the child and knowing whether acceleration in language function does occur. Where there is a family history, particularly in the males, of language retardation with eventual normality, the probabilities that this is a temporary defect are high. Where there is no such family history, and if some prenatal, paranatal, or postnatal pathology raises the suspicion of brain damage, determination as to whether the speech lag is permanent or temporary may have to await the emerging facts of the child's development. Similar reasoning applies also to lags in coordination and in acuity of perceptual organization.

Temporary lags. Having determined that the developmental defect is transient and that the child is of normal intellectual capacity, the psychiatrist must then prevent behavioral deviance as a consequence of the stress caused by the developmental disturbance. Where there is a language lag, the onset of expressive language may be delayed to age 3, 4, or 5, with normal receptive language. Such a child is partially but not completely cut off from interaction with his peers; he is able to understand what is said to him but is not able to convey his own desires, thoughts, emotions. Depending on a number of other factors, among which temperamental issues and environmental handling are prominent, the child may develop a variety of de-

fensive behaviors or fears and anxieties or may be brought through this period with a virtual absence of secondary behavioral reactions. He may, for example, become intensely dependent on his mother or members of the immediate family who must act as interpreters to the world. He may become aggressive, protecting himself by pushing, grabbing, and fighting in play situations with his peers. He may become anxious as soon as a situation is unfamiliar and deviates from the routine, and he may exhibit his own typical panic reaction, whether it be crying, kicking, biting, or throwing tantrums, or somatization of his anxiety. He may, on the other hand, involve himself in constructive peer interactions, becoming so adept at receiving and giving nonverbal cues that he is a useful companion in block play, putting puzzles together, painting on easels, riding tricycles, or group games with rules.

Permanent defects. Disturbance in development involving permanent defect may involve autism, mental retardation, and major physical handicaps, such as blindness, deafness, and motoric defects such as polio muscular weakness, muscular dystrophy, or cerebral palsy. In each situation the behavioral reaction depends on the severity of the handicap and what this permits and precludes in terms of participation in normal child groups. The behavioral reaction also depends on temperamental and environmental factors. The handicapped child is under greater stress than the child with normal capacities. There are more situations in which demands are made of him that are beyond his capacity to accomplish, whether in terms of interpersonal responsiveness, intellectual comprehension, or physical accomplishment. As a consequence, he has more experiences than the average child of failure, of expressions of derogation or annoyance from people in his environment, of rejection and exclusion from peer groups. The degree to which he is rejected and excluded may depend more on his temperamental organization than on the fact of the defect itself, and his reaction to the stress may be in the direction of exaggeration of temperamental quality, be it dependency, aggression, compliance, or disorganization.

Adjustment Reactions

Adjustment reactions in childhood must be approached as an interactional concept. One must define the two interacting dimensions: on the one hand, the structure of the organism doing the reacting; on the other hand, the nature of the environment in which positive adaptation or maladaptation occurs.

Temperamental qualities. If one is dealing with a child without organic defect, there still remains the necessity of identifying his temperamental qualities, as these will be an important determinant of his interaction with the world about him. His temperamental organization may be a determinant of the effective environment. For example, an infant with a low thresh-

old of reactivity in an environment that includes much noise of varying ranges in intensity may respond with irritability, crying, or panic reaction; an infant of high auditory threshold in the same objective environment does not have auditory irritation as part of his effective environment. Similarly, a child of high activity level may find a particular milieu to be stressful, whereas a youngster of low activity level finds the same objective environment benign. In addition, the temperamental individuality of the child may influence the conduct of other persons, thus affecting his environmental experiences. An infant who is intense in his activity, is persistent, and cries loudly and long when hungry or uncomfortable may receive faster and more frequent nurturing responses from his mother than an infant whose hunger cry is softer, who stops crying temporarily if not responded to or if distracted by being picked up or amused with a rattle.

The hyperactive toddler may evoke a great many scoldings, expressions of annoyance, and physical confinement to a playpen; the physically less active child of the same age is less likely to get into dangerous situations or disturb the comfort of others of the family. The family's responses depend also, of course, on a number of other environmental circumstances, including the personalities of the parents. In any given set of circumstances, the child's temperamental attributes play an important determining role in the handling he receives and, consequently, his effective environment.

Temperamental individuality in childhood has been studied in a research project engaged in by Thomas, Chess, and Birch over the past 10 years. In the course of the study, children's behavioral reactions have been examined from birth onward through multiple interviews with parents and teachers, observations of the child in school, and standardized testing procedures. From this data an inductive analysis of temperamental qualities has been drawn. The following temperamental attributes have been identified: (1) activity level—the motor component present in a given child's functioning; (2) rhythmicity—the predictability of such functions as hunger, feeding pattern, elimination, and sleep-wake cycle; (3) approach or withdrawal—the nature of the response to a new stimulus, such as a new food, new toy, or new person; (4) adaptability—the speed and ease with which a current behavior is able to be modified in response to altered environmental structuring; (5) intensity of reaction—the amount of energy used in mood expression; (6) threshold of responsiveness—the intensity level of stimulation required to evoke a discernible response to sensory stimuli, environmental objects, and social contacts; (7) quality of mood—pleasant, joyful, friendly behavior as contrasted with unpleasant, crying, unfriendly behavior; (8) distractibility—the effectiveness of extraneous environmental stimuli in interfering with or in altering the direction of ongoing behavior; and (9) attention span and persist-

ence—the length of time a particular activity is pursued by the child (attention span) and the continuation of an activity in the face of obstacles (persistence).

Temperament and adaptation. These temperamental qualities have been scored on a three-point scale, and an assessment has been made as to their consistency over time and their relationship to the presence or absence of behavioral disorders in the study of children. It has been found that over the first 2 years of life temperamental stability is high from the point of view of both qualitative analysis and quantitative statistical assessment. Certain temperamental clusters are associated with stressful parent-child interactions and with a high probability, though not a certainty, of the development of behavior problems. Other temperamental clusters are associated with a high probability of benign child-environment interaction and a low probability of the presence of behavior disorders.

The temperamental cluster most likely to be a nucleus of maladaptation and stressful response to the increasing demands for socialization as a child moves from early to late infancy and through childhood contains the following attributes: high degree of reactivity, a withdrawal response to new situations, slow adaptation, and intensity of mood. Such infants and children respond to new situations, new demands, and new people by withdrawal and negative behavior of an intense degree. When given an opportunity for gradual familiarization, the negative behavior diminishes, and the child may eventually become well adapted to the new demand. For such a child, multiple changes occurring simultaneously are particularly stressful. Also stressful are situations that require immediate adaptation without a period of acclimatization and familiarization. In contrast, a child whose response to new people, places, toys, and schedules is an immediate positive reaction or who is speedy in his rate of adaptation does not find a multiplicity of simultaneous changes at all stressful.

The vulnerable youngster is likely to present behavior difficulties with a move to a new home; with the introduction of a new individual into the household, whether it be a new adult or a baby; with a change in routine procedures, such as a new bed; with his introduction to a new organization of his day and new circumstances of living, such as starting nursery school or play group. Given an opportunity to familiarize himself with the change, the child's behavioral reaction is temporary. However, if these changes succeed each other rapidly or involve losses of important individuals, with uncertain substitutes and arrangements, the reaction may be one of stress and maladaptation.

Parental handling. Consistency in parental handling of children may also have varied consequences, depending on the temperamental organization of the child. The youngster with initial negative reactions, with a long adaptation period—in short, the vul-

nerable child described above—finds parental inconsistency considerably more disturbing than the easily adaptive, positive mood child. The vulnerable child requires consistent, persistent clues in order to react with the appropriately adaptive behavior. If parental demands for performance of specific routines, for behavioral inhibition, for higher level social responses are unclear, the youngster may be unable to develop routine reactions of an acceptable nature. He may, instead, move into negativistic teasing, or he may develop behavioral patterns that reflect his confusion about the signals given to him. For example, the child who has developed an extensive bedtime routine may be faced with a parental demand that he go to bed more quickly and that he omit one of the many stories or one of the many drinks of water. The youngster responds to this new demand initially by loud protest. After a half hour of tantrum, the parent capitulates. The signal to the child now is that he must demand longer in order to maintain his usual routine. Repeated ineffectual disciplinary parent-child interactions have the effect of perpetuating this maladaptive behavior on the part of the child. On the other hand, the child who temperamentally is more quickly adaptive can easily adapt to parental inconsistency with regard to bedtime routine. Similarly, parental inconsistency in regard to availability or nonavailability to the child at certain times and under certain circumstances, in regard to the degree of disapproval expressed toward certain behaviors, and so forth, constitutes a stress for the vulnerable child but does not constitute a stress for a child of other temperamental make-ups.

Other stresses linked to temperament can be summed up as follows. The demand for extended periods of motoric quietude constitutes a stress for the hyperactive child and may result in behavior disorder characterized by disorganized running about. Parental disapproval of the child's inability to carry through tasks set for him constitutes stress for the highly distractible child, who cannot keep in mind the directions given him in the face of other stimuli that compete for his attention. The demand made on a highly persistent child that he shift activities immediately on parental command represents a stressful demand that is more likely to evoke a tantrum or other maladaptive response than it is to bring about compliance.

Physical illness and handicaps. Physical illness and physical handicaps involve special stress situations in childhood. In such circumstances the pediatrician or general practitioner treating the child acts as the preventive psychiatrist by his clarity in interpreting the nature of the acute illness and the degree of permanent handicap if there is a sequela. One need not assume that the need for activity limitation, as in cardiac defect, or the necessity of a permanent medical regimen, as in childhood diabetes, or the inability

to join in athletics, as in postpolio dysfunction, necessarily leads to maladaptation.

Positive adaptation by the child to realistic limitations imposed by illness starts with the comprehension by the child of the precise nature of the illness. This understanding must be in terms appropriate to the child's age and related to his functioning. A 5-year-old can learn that chocolate gives him an itchy rash; the diabetic child can learn to refuse cake at a party; the youngster with cardiac restriction can learn to recognize the first signs of fatigue. Many chronically ill children can be relied on to take their own medication and thus attain a sense of independence despite physical limitation. More severe motoric handicaps, such as cerebral palsy and athetosis, demand an exceedingly careful appraisal of the degree to which nurturance and servicing is required. The key to healthy mastery of the fact of handicap lies in correct parental estimation of the degree of handicap, their orientation to teaching the child techniques for caring for himself to the fullest degree possible, and their matter of fact giving of the help that is necessary. With this attitude as a model, one has the greatest possibility of the child's avoiding the mechanisms of secondary gain, overdependence, controlling behavior, bravado or other inappropriate insistence on being independent, fearfulness, hostility, etc. Where such behavior patterns have become established, redefinition of appropriate parental attitudes and parent guidance is needed, and at times direct psychotherapy with the child is beneficial.

Hospitalization may or may not be a stressful experience for a child. A gregarious youngster with easy adaptability finds a pediatric ward a pleasant experience. With elective hospitalizations, it is possible to acquaint the child ahead of time with the procedures to take place. Stress is more likely to occur with a child who does not adapt quickly to new experiences, who is not placed with other pediatric patients, or whose depth of illness or the emergency nature of the hospitalization makes for the likelihood of apprehension and panic. Under the latter circumstances, the posthospital period may require psychological as well as physical recuperation.

Adoptions. Adoption may require some careful consideration as a possible source of stress. In general, however, behavior problems in adopted children and negative child-parent interactions tend to be the same as would arise in a natural parent-child pair, given the same temperamental and environmental issues. In adoptive situations, the issues that arise may be intensified because of the parents' feeling of the child's specialness; thus, parental tendencies toward indulgence or overprotection may become more pronounced. Child tendencies toward controlling behavior are more potent with the parent who feels uncertain of his right to parenthood. The child who is adopted in an attempt to cement a disintegrating marriage has a high potential for maladaptability; the

same is true of the child conceived in the same vain hope.

Management requires the same diagnostic analysis and handling of the given behavior as would be the case were adoption not a fact.

Presenting Psychiatric Problems in Infancy and Childhood

Since the human organism's ability to react is limited by his developmental level, presenting problems tend to group themselves by age. Just as pain is an expression of diverse organic malfunction, in a similar fashion diverse psychiatric disorders of infancy and childhood have a limited number of pathways of expression.

Infancy (birth to 2 years)

Developmental disturbance. Presenting complaints may pertain to general retardation in all or some developmental areas. These may involve failure to thrive; failure to sit, stand, or walk in accord with the normal time tables; delay in language; absence of age-appropriate affective behavior, such as recognition of familiar people and formation of affectionate bonds. Table I contains a summary of some of the landmarks of normal behavioral development. These time tables may be considered as means or averages, and normal development actually falls within a rather broad range. However, serious deviation from these norms is a sign of developmental retardation.

Management of developmental failures. The decision that failure to thrive or failures to attain normal developmental milestones are psychological in origin is to be made with caution. Organic causation must be ruled out by appropriate medical and neurological investigation. In addition, there must be identification of psychogenic etiologies, which can be determined by careful assessment of patterns of maternal care and a therapeutic trial of extra affection and physical stimuli through cuddling, stroking, and the often prescribed tender loving care.

Motoric delays call for neurological investigation to rule out static or degenerative neurological disease or muscular pathology. In the presence of an adequate nutritive state, one must chart the developmental curve over time in order to decide whether the delay is temporary or a sign of mental retardation.

Delays in language and affective development should be handled by first making sure that the environment supplies the affection and conversation necessary for the optimum development of the child's capacities. Where the delay is a temporary organic lag in maturation, the psychiatric management is directed toward avoidance of secondary defensive behavioral disorder.

Aberrant behavior. A second group of presenting problems in infants pertains to aberrant patterns of behavior. In the motoric area, one may find hyperactivity or hypoactivity; rhythmic activity, such as

TABLE I
Landmarks of Normal Behavioral Development

Age	Motor Behavior	Adaptive Behavior	Language	Personal and Social Behavior
Under 4 weeks	Makes alternating crawling movements Moves head laterally when placed in prone position	Responds to sound of rattle and bell Regards moving objects momentarily	Small, throaty, undifferentiated noises	Quiets when picked up Impassive face
4 weeks	Tonic neck reflex positions predominate Hands fisted Head sags but can hold head erect for a few seconds	Follows moving objects to the midline Shows no interest and drops objects immediately	Beginning vocalization, such as cooing, gurgling, and grunting	Regards face and diminishes activity Responds to speech
16 weeks	Symmetrical postures predominate Holds head balanced Head lifted 90 degrees when prone on forearm	Follows a slowly moving object well Arms activate on sight of dangling object	Laughs aloud Sustained cooing and gurgling	Spontaneous social smile Aware of strange situations
28 weeks	Sits steadily, leaning forward on hands Bounces actively when placed in standing position	One-hand approach and grasp of toy Bangs and shakes rattle Transfers toys	Vocalizes "m-m-m" when crying Makes vowel sounds, such as "ah," "eh"	Takes feet to mouth Pats mirror image
40 weeks	Sits alone with good coordination Creeps Pulls self to standing position	Matches two objects at midline Attempts to imitate scribble	Says "da-da" or equivalent Responds to name or nickname	Responds to social play, such as "pat-a-cake" and "peek-a-boo" Feeds self cracker and holds own bottle
52 weeks	Walks with one hand held Stands alone briefly		Uses expressive jargon Gives a toy on request	Cooperates in dressing
15 months	Toddles Creeps upstairs		Says 3 to 5 words meaningfully Pats pictures in book Shows shoes on request	Points or vocalizes wants Throws objects in play or refusal
18 months	Walks, seldom falls Hurls ball Walks upstairs with one hand held	Builds a tower of 3 or 4 cubes Scribbles spontaneously and imitates a writing stroke	Says 10 words, including name Identifies one common object on picture card Names ball and carries out two directions, for example "put on table" and "give to mother"	Feeds self in part, spills Pulls toy on string Carries or hugs a special toy, such as a doll
2 years	Runs well, no falling Kicks large ball Goes upstairs and downstairs alone	Builds a tower of 6 or 7 cubes Aligns cubes, imitating train Imitates vertical and circular strokes	Uses 3-word sentences Carries out four simple directions	Pulls on simple garment Domestic mimicry Refers to self by name
3 years	Rides tricycle Jumps from bottom steps Alternates feet going upstairs	Builds tower of 9 or 10 cubes Imitates a 3-cube bridge Copies a circle and a cross	Gives sex and full name Uses plurals Describes what is happening in a picture book	Puts on shoes Unbuttons buttons Feeds self well Understands taking turns
4 years	Walks downstairs one step per tread Stands on one foot for 4 to 8 seconds	Copies a cross Repeats 4 digits Counts 3 objects with correct pointing	Names colors, at least one correctly Understands five prepositional directives—"on," "under," "in," "in back of" or "in front of," and "beside"	Washes and dries own face Brushes teeth Plays cooperatively with other children
5 years	Skips using feet alternately Usually has complete sphincter control	Copies a square Draws a recognizable man with a head, body, limbs Counts 10 objects accurately	Names the primary colors Names coins: pennies, nickels, dimes Asks meanings of words	Dresses and undresses self Prints a few letters Plays competitive exercise games

body rocking and head banging; bizarre activities, such as unusual twisting motions of the hands or body. Sleep problems include awakening at frequent intervals, difficulty in falling asleep, nightmares, and night terrors. The management here described is directed toward the diagnostic categories of reactive behavior disorders and mild neurotic traits. The above-mentioned behaviors may also occur in more severe psychiatric disorders which should be considered in the differential diagnosis.

Unusual motoric activities often occur in the hyperactive child who is not provided ample opportunity for motoric expression. There should be an assessment of the degree to which large muscle movement is made possible in the organization of the environment and whether the youngster is confined for long periods to crib, carriage, or playpen. Safe opportunities for active crawling or running about may reduce the abnormal motoric behavior.

Broken sleep may be due to the fact that a child has less than average physiological need to sleep. In such cases, short naps and long periods of wakefulness are present from birth. The frequent awakenings, although inconvenient for the parents, are not abnormal. Children with average sleep needs had previous periods of sleeping through the night. The change in sleep pattern may be initiated by illness that caused discomfort at night. The broken sleep in such a case should be considered a habit pattern. In both these instances, the frequent awakening is not to be construed as a sign of fearfulness or insecurity unless there is independent evidence of anxiety. If parental handling has been punitive, however, the child may have acquired apprehension that the parent will be angry. In such a situation the recommendation is for the parent to eliminate his anger over the fact that the youngster has disturbed his sleep and to refrain from reinforcing the habit of awakening by going in to look at the youngster. This is the type of situation in which the child should cry it out.

The child who has fear at night demonstrates this by nightmares or by being afraid to stay in his dark room alone. Management of this problem requires two phases: (1) comforting the youngster when he is afraid and (2) seeking to determine and remove the source of stress in his daily life. In nightmares the child awakens crying from a bad dream. In night terrors the child does not actually awaken and does not recall a dream; when comforted, he may open his eyes, then fall asleep again with no recollection of the event.

Eating disturbances in infancy may involve refusal of new foods, with a consequent restricted diet; refusal of solids at expected ages, with acceptance at age 1 year, or later, of pureed infant foods only; capricious food acceptances or in the extreme case, pica.

Psychogenic eating refusals in infancy are rare today. The easy availability of a large variety of in-

fant foods and vitamin supplements has so eased this aspect of child care that it is a rare mother who becomes tense over infants' food refusals. The mother-child battle at mealtime is a picture of a past generation.

Odd food tastes call first for investigation of the possibility of organic digestive pathologies. In the absence of an organic basis for a self-imposed restricted diet, the infant may require a period of familiarization with new tastes or new food consistencies before accepting them into his diet. There may have been not enough exposures to the new circumstance to permit acceptance.

Pica is the eating of nonfoods. There may be a selective eating of dirt or plaster, or the pathological eating preferences may involve ingesting any and all substances that can be mouthed. The danger of accidental poisoning with serious consequences is high with such children, and chronic lead poisoning is a particular danger. In the absence of major psychopathology, one strongly suspects affectional neglect. Appropriate management is to supply an abundance of affection and mothering.

Unusual affective behavior may include excessive dependency on one or a few individuals, fear of separation from mother or mother substitute, fears of or unusual seeking out of specific people, places, noises, tactile sensations, or odors.

In the absence of major psychopathology, the most frequent source of such behavior is some traumatic event, a transient situation, or stress that caused strongly conditioned reactive behavior designed to protect against repetition of the event. If a single traumatic event caused the reaction, recovery occurs over a period of time, during which the child is exposed to his usual routine of activities with gradual reduction of the special comforting measures employed while he was acutely distressed. When there was a succession of traumas, such as a series of deaths of individuals important in the child's life, or a number of frightening experiences, active intervention may be required. Opportunity should be afforded the youngster to play or talk out his experiences. A planned schedule of activities in which the new is closely associated with the familiar place, person, or thing may aid the youngster. Direct psychotherapy may be required.

Preschool age (2 to 6 years). In the preschool age, children may present problems that occur during infancy. These problems may have started in infancy and be brought to notice now because of their persistence, or they may first make their appearance during the preschool age period. As the child grows and matures, additional behavior complaints may appear. Ideational components may now characterize the youngster's actions, being at times causative of the problem behavior or secondary to it. In the latter case the conceptualization may represent the child's attempt to understand his own be-

havior. Parental formulations and interpretations, representing their attempts to cope with the behavior disorder, may be the origin of the child's concept of his motivations. Nightmares are now possibly expressed as dreams of burglars, monsters, or wild animals; separation anxiety is expressed as worry of injury to the mother during the child's absence.

Sleep and eating problems. Old behaviors may continue, but they are given new significance and become greater management problems because the older child has more latitude of action. For example, new complaints with regard to sleep are of the following type: the child comes into a parent's bed nightly or does not fall asleep unless the parent is sitting at his bedside; an extensive nighttime ritual is demanded by the child; if this is refused by the parent, there is a tantrum. Self-imposed food restrictions become extreme, and the mother prepares a different meal for the child than for the remainder of the family; the youngster balks at coming to the table and at using prescribed table manners. This type of sleep or eating problem generally represents an arena of dependency-hostility. The antagonism is the basic problem. Often one may find on further history taking that there is a struggle over all or most routines.

Management requires analysis of the parent-child relationship. Guidance is of aid to the parent whose management is inappropriate to the child's temperament or age. Where personality difficulties in the parents are causative or where child reactions have become fixed, psychotherapy of child or parents or all three may be needed.

Compulsive overeating severe enough to cause obesity and not based on endocrine dysfunction calls for careful appraisal of the mother-child relationship, with particular attention to the combination of strong dependency and strong hostility. Simple advice is usually insufficient. A trial at psychotherapy is recommended, but prognosis is poor.

Pica continuing into the preschool age has increasingly morbid connotations and is likely to be associated with mental retardation or brain injury or gross physical and affectional neglect. Measures to be taken must be appropriate to the diagnostic conclusion reached.

Language problems. In the language area, new presenting problems may include stuttering. In many cases the stuttering youngster comes from a family with a history of this disability. Although a familial component may be under suspicion, the precipitating cause is often a traumatic circumstance or the simultaneous occurrence of a number of demands for higher stages of socialization or impulse control. Reducing the sources of stress may be sufficient to decrease or eliminate the stuttering.

Immature speech patterns may persist. If these patterns do not show a strong trend toward spontaneous correction as the child approaches school age,

speech evaluation and possibly speech therapy may be appropriate.

Affective problems. Affective disorders may become more pronounced or first appear in the preschool age period. Unrelatedness or inadequate or inappropriate relatedness to adults, children, or both may be the presenting complaint. The behavior may be described as withdrawal, excessive demands for personal attention, or wild and noisy response to attention. There may be outbursts of silliness, impulsive destructiveness, or rages—all out of proportion to or in the absence of a precipitating event.

When such behavior occurs in a child who is not suffering from major psychopathology, one seeks to find an explanation in environmental stress. The cause may be found in rivalry over the birth of a sibling, profound parental discord, physical or mental illness in a parent that results in uncertainty of daily care and of care-takers. In some cases one may discover cruel and unusual treatment of the child by adults. Management calls for arranging a stable and warm substitute environment for the child.

A host of fears and phobias at times make their appearance in this age group: fears of animals, fire engines, riding in elevators, people dressed in specific fashions. In reaction to such stimuli, the youngster may run away, cry loudly, whine, demand to be held, or hit and attack his would-be protector.

Management of such symptoms requires a determination first of whether the phobic reaction is an appropriate reaction to a traumatic situation. Does the child have many fears? Is the particular phobia symbolic in nature? A traumatic reaction calls for time and reassurance. A basically fearful child or a youngster with symbolic expression of fears may require direct psychotherapy.

Elimination problems. Problems of elimination may present themselves, either because the child maintains earlier behaviors despite advance in age or because of regression from achieved levels. Diurnal enuresis, soiling, withholding of feces, fear of defecation or of strange toilets may occur. The first step in management requires determination as to whether an organic base for dysfunction exists.

Hitherto unrecognized anomalies of the urinary tract may be found. The behavior reaction to large, infrequent, and painful stools may stimulate a medical investigation that identifies megacolon or other bowel disorder. Only after it is clear that there is no organic cause should the issue be approached as a problem of toilet training.

Motor problems. In the preschool age period, tics may make their first appearance. Usually the first tic is ushered in by a related circumstance: an eye blink by eye irritation, a shoulder shrugging by a falling clothing strap. The child is frequently of the high activity type. The tic may shift from one muscle

group to another and lose its correlation with the precipitating stimulus.

Appropriate management seeks to identify stresses in the environment that may be excessive—overly great demands for movement restraint, family dislocation, a new sibling, contradictory parental expectations, etc. Treatment consists of reducing sources of stress. In addition, tranquilizers may be helpful. In extreme cases of multiple tic, there may be flinging of arms and legs, with peculiar barking sounds. This syndrome is termed Gilles de la Tourette's disease. Medicative therapy is called for.

School age through preadolescence (6 to 13 years). Most of the behaviors discussed under presenting problems of infancy and preschool age may present themselves in the school age period.

School and learning problems. Additional behavior disorders typical of this age period include those brought out by the demands of school attendance and of formal learning. Hitherto unrecognized dependencies and separation anxieties appear as presenting problems as a result of the demand for school attendance. There may have been previous expressions of separation anxieties—a preschooler who would visit friends only if mother remained or parental avoidance of going out at night because of the child's crying. When a child is fearful about going to school or develops somatic complaints, such as bellyaches or headaches on school mornings or while in school, parents are advised to bring the child for diagnostic study.

Except under extreme circumstances, management requires that the child be maintained in regular school attendance, thus mobilizing his desire to rid himself of his symptoms. Parental guidance or direct psychotherapy may be required.

Learning difficulties may make their first appearance in the school age period—problems of dyslexia, brevity of attention span, and inability to concentrate. Difficulties in relating to other children or to persons in authority may be recognized for the first time, and the child may be brought for consultation. Often the complaints come from the school, where age-appropriate expectations are clearer and more objective and where deviance from the remainder of the class becomes an interference with teaching. In the child's preschool years, parents often have accommodated to the deviant behavior and have closed their eyes to or explained away the child's isolation from his neighborhood peer group.

Psychopathologies. At times major psychopathologies are first brought to notice when the child enters school. Mental retardation, behavior disorders due to brain damage, and psychoses must be differentiated from reactive or neurotic behavior disorders. Elective mutism, protective inhibition of activity, temporarily disorganized behavior due to multiple simultane-

ous stresses—all may require such differential diagnosis.

Inappropriate attitudes may begin to make their appearance in this age group: dependency, excessive independence, hostility, negativism, excessive teasing, and overly great concern with pleasing. These require detailed analysis of the inappropriate parent-child interaction that initiated and perpetuated the behaviors. Parent guidance and possibly direct psychotherapy with the child may be called for.

Micropsia is a rare occurrence and consists of perceptual distortion in which objects or people appear to shrink or seem to be retreating to a distance. This phenomenon is to be distinguished from hallucination due to (1) organic illness—drug toxicity, hypertension, hyperpyrexia, etc.—or (2) childhood psychosis. The hallucinosis of micropsia is to be found in nonpsychotic children in stress situations, and the appearance of the strange phenomena frightens the children. It is often difficult to determine whether the terror is primary or secondary to the misperception.

Management requires determination of the environmental and interpersonal factors causing the stress, and a decision as to whether environmental manipulation is sufficient to reverse the problem or a psychotherapeutic course is also required.

Antisocial behavior. School age may be the initial period of a host of antisocial and destructive acts—fire setting, stealing, vandalism. It is necessary to determine whether these behaviors are social in origin, are indicative of major pathologies, or represent failure of sufficient training in impulse control. On the other hand, they may represent hostile acting out of attitudes that are felt toward parents but cannot be directed toward them for intrapsychic reasons. Management is determined by the cause and may include direct social training, institutionalization, parent guidance, or direct treatment in whatever combination is required.

Suggested Cross References

See Section 38.2 for further information about normal child development. Further information regarding childhood psychosis and brain disorders may be found in Chapter 42, while the psychoneurotic and personality disorders are discussed in detail in Chapter 41. Sections 40.3, 40.4, 40.5, 40.6, and 40.7 in this chapter deal with children's reactions to hospitalization, speech and language disorders, enuresis, nail biting and thumb sucking, and conduct disorders, respectively. Detailed information regarding the techniques used for the diagnosis of the developmental and reactive disorders that were discussed in this section may be found in Chapter 39, on assessment in child psychiatry. Treatment in child psychiatry is further discussed in Chapter 43.

40.2 HEALTHY RESPONSES, DEVELOPMENTAL DISTURBANCES, AND STRESS OR REACTIVE DISORDERS. II: ADOLESCENCE

EDWARD J. HORNICK, M.D.

Adjustment reactions of the adolescent are the rule rather than the exception. Disturbed reactions may be expected also from family members and from society at large. All three groups are under stress. As Sol Ginsburg once wrote, "Adolescence is tough on everybody." This ferment is also useful to the adolescent, his family, and society.

Early in adolescence the source of disturbance is more likely to be reactive to physical changes and the intrapsychic meaning of these alterations. Later in adolescence the issue of identity formation is central.

All manner of pathology can be seen in all degrees— anxiety, depression, mania, schizoid and schizophrenic illness, perversions, alcoholism, addiction, behavior disorders, accidents, and psychosomatic affections. It is vital to a valid interpretation of any adolescent behavior that it be seen in its developmental process against a background that includes the physiology and psychology of adolescence, the family dynamics, and the wider scope of culture itself.

Normal Development

At no stage in growth must one be more cautious in assessing disturbances in development than at adolescence. One pitfall is failure to respect the variety of paths taken by adolescents in their interior and ex-

terior journey toward maturity. In a study of teen-aged boys, the Stolzes pointed out that the physical and physiological process occurs over a range of 4 years. However, one boy may complete his entire growth spurt and primary and secondary sexual development in 3 months. Another may change gradually over the 4 years. One boy may grow at 12 and another at 16. Nor is there any regularity in the order in which physical changes take place. This variation is but a shadow of the complexity of the process when psychological, educational, social, and cultural factors are folded into the picture along with the physical ones. There is even the suggestion by Rosenbaum that emotional factors may have some important bearing on the timing of physiological changes.

A second concern is the special reactions of the adult community to teen-agers. It is probably safe to say that adolescents are more commonly scapegoated than any other age group. Professionals, including psychiatrists, are not immune to this practice. The adolescents' preoccupation with themselves, their volatility, their burgeoning sexuality, and especially their negativism and acting out to define societal limits cast them easily into the scapegoat role. Middle-aged psychiatrists, even more than middle-aged parents and teachers, cannot afford the understandable irritability and impatience that beset an adult challenged by living reminders of old conflicts. Santayana once said he wouldn't mind repeating his youth were it not for all those trap doors. There is a special advantage, however, to the role of psychiatrist. He can be a participant-observer in a highly personal adventure in self-realization, an experience that can provide new insights for the examiner as well as the examined.

Changing values in a culture are mediated by ever new generations of adolescents devising differing values from their parents as they mature. This momentum for necessary change has its psychological frictions in disturbed and disturbing adolescents, but not all that is disturbing is disturbed.

This point deserves underscoring. The line between normal and abnormal is very vague. Most adolescents are healthy physically and emotionally, yet *all* adolescents have assorted situational, developmental, and adjustment reactions. Indeed, Anna Freud said, "Adolescence is by its nature an interruption of peaceful growth, and the upholding of a steady equilibrium during the adolescent process is in itself abnormal." One may expect the adolescent to behave in an inconsistent and unpredictable manner, and one may be concerned about the child who shows no alteration in behavior through adolescence. In the same paper she pointed out that it is not yet possible to predict from a knowledge of earlier life development what adolescent development will bring. There are simply too many new variables. The arena of life in which adolescence is played is much larger than the family.

It introduces political, social, and sexual problems of such immensity that they become differences of kind.

Personal Disturbances

Sexual impulses. The awakening of sexual feelings which accompany the development of sexual hormones and organs is usually a source of difficulty as well as pleasure to the young teen-ager. The conflicting and often contrasexual mores of the Western middle class—doctors included—represent the climate in which this development occurs. Puberty follows a relatively peaceful period, in which boys and girls cluster separately around less explosive activities. The poet Yeats described how he would “get up at dawn and having stripped leap to and fro over a stick laid down upon two chairs, and hardly know, and never admit, that he had begun to take pleasure in his nakedness.”

Often there is a preoccupation with the changing parts: the relative size and position of the breasts in girls, the amount of mammary fat in boys, the amount and placement of bodily hair, the size and shape of the penis, the color and droppage of the testicles. Indeed, the whole body is subject to careful scrutiny, and the slightest alteration—such as a mole, a spot of acne, or a cowlick that won't plaster down—comes in for anxious observation. This has its social overtones. There is intense comparison with others in class, club, or showers. When a boy of 14 or a girl of 12 is fearful about handling such marks of growth, he or she may be impelled to avoid members of the opposite sex or may be driven to test out the new equipment. It is important to remember that the teen-aged boy lags about 2 chronological years behind the teen-aged girl physiologically, and this accounts for the dating pattern of older boys with younger girls.

Talk among boys runs to pornography and wild fantasies of what feats of sexual prowess one would like to accomplish. Girls at puberty are more prone to rich private fantasies. Sometimes these preoccupations interfere with learning, especially in the seventh and eighth grades, or lead to mild and usually transient anxieties, depressions, or hypochondriasis. There are periods of frenetic mixing or solitude, both covering a volcano of sexual thoughts and feelings.

Anna Freud described intellectualization and asceticism as two common adolescent defenses to cope with the instinctual forces. Intellectualization is involvement in ideas and books, in debating issues rather than living them, that serves most youngsters to stall direct sexual experimentation and experience until they are ready for it. Asceticism is a strategic retreat into purity, grand ideals, and a renunciation of body pleasure. This usually means giving up masturbation, a practice heavily weighted with forbidden fantasies for both sexes. Both intellectualization and asceticism may hypertrophy to a point where they are disturbing to the adolescent.

A familiar junior high school ritual among boys is clubbing together in secret groups. The secret is that they fear girls, don't trust their parents, and need to lean heavily on each other for reassurance. They indulge in homosexual play, “goosing,” genital pinching, and mutual masturbation, usually scored by themselves as masculine adventure. For some, the fears of heterosexual contact are so great that they remain locked at this stage of development. Persistent preference for homosexual partners after the age of 16 is highly suspect. A boy in the throes of dealing with a homosexual impulse often presents a considerable amount of anxiety, a condition that has been labeled homosexual panic. However, the cause of such a condition may be overdependency, fear of superior force, retreat from real or fantasied heterosexuality, masturbatory panic, or, finally, a true terror of homosexual contact.

Masturbation seems to be universally associated with guilt among adolescents of both sexes. This is true regardless of the educational exposure of teenagers because the guilt is tied to forbidden unconscious fantasies accompanying the masturbatory impulse or act.

Depression and excitement. Mood swings are common at all ages, but they appear particularly rapid and inexplicable in adolescents. It was long believed that true depression only became possible after the teen years, but there are now many documented cases of adolescent depression. Affective changes are likely to follow any disappointment—in oneself, in one's peers, in one's parents, in one's ideals. Bursts of vigorous and even violent activity may alternate with apparent laziness or inability to work or study. By and large, these happenings in the teenager are commonplace. The incidence of suicide does rise in the late teens and then falls off. A very common sign of aggression turned against the self is the high adolescent accident rate—cars, household, and sports—from the combined activity and self-punishment at this age.

Delinquency. Michaels noted that delinquent behavior occurs in a complex psychosociobiological matrix. The earlier and the more persistent its appearance, the more one must consider a constitutional cause. The later and more transient the delinquency, the more it is likely to stem from a neurotic factor. It was also Michaels who differentiated a form of delinquency associated with persistent enuresis, for which he suggested the rubric of impulsive character.

Redl and Wineman provided a careful delineation of the techniques of the delinquent ego, notably an ego whose strength lies in its resistance to change. Among these are the strategy of tax evasion (no guilt), the search for delinquency support (enlisting other peers to shore up the delinquent value structure), and the mechanized warfare with change agents (fighting therapists).

It is certain, however, that misbehavior becomes possible on an enlarged scale at adolescence and that almost all adolescents experiment with it to some degree. The more familiar battlegrounds in middle class youngsters are the curfew, choosing of one's own dress and friends, truancy, and pilfering. Whatever the behavioral component, the youngster must be studied longitudinally and cross-sectionally to determine what developmental task is being solved, however inappropriately, in an antisocial fashion.

Schizoid and schizophrenic manifestations. The total impact of puberty and psychosocial change during adolescence often produces a clinical picture of social withdrawal, depersonalization, and derealization, leading occasionally to full blown dementia praecox. All shades of this symptom complex demand special care in their precise diagnosis, treatment, and prognosis. For many adolescents this venture is an experiment in self-development. French and Kasanin have described two young people who had brief psychotic episodes as they broke out of particularly crippling family situations. What is true for psychosis is all the more true for the adolescent who essays various schizoid maneuvers in his or her search for self.

Identity. Erikson centered his interest in the late adolescent on achievement of ego identity in his book, *Identity and the Life Crisis*. "The conscious feeling of having a personal identity is based on two simultaneous observations: The immediate perception of one's self-sameness and continuity in time; and the simultaneous perception of the fact that others recognize one's sameness and continuity." This identity is the crystallization of innumerable conflicts among ego, id, ego-ideal, and superego achieved by the adolescent through role experimentation.

In defining late adolescent pathology, Erikson added several viable new phrases to the vocabulary. "Identity diffusion" is a failure of the adolescent or young adult to arrive at a cohesive self-and-reflected-self-awareness in his total life scheme. It usually becomes manifest "at a time when the young individual finds himself exposed to a combination of experiences which demand his simultaneous commitment to physical intimacy, to decisive occupational choice, to energetic competition, and to psychosocial self-definition."

The "psychosocial moratorium" is the prolongation of adolescence into the twenties while the individual pauses to form his fragments of identification into a consistent whole. This is societally sanctioned in college and particularly in postgraduate education.

Often parents' conflicts find expression in a "negative identity," "an identity perversely based on all those identifications and roles which, at critical stages of development, had been presented to the individual as most undesirable or dangerous, and yet

also as most real." A mother with unconscious ambivalence toward an alcoholic brother may respond selectively to those traits in her son that tend to repeat her brother's fate, with the result that the son becomes an alcoholic. "Many a late adolescent, if faced with continuing diffusion, would rather be nobody, or somebody bad, or indeed, dead—and this totally, and by free choice—than be not-quite-somebody."

Family Disturbances

Children between 3 and 6 years of age complete one round in the solution of the oedipal situation. At adolescence the problem is recreated with new post-pubertal talents for action, with the actual parents around as tempting objects, and often with parents who react to them, positively or negatively, in a sexual fashion. These include the father who won't let his daughter of 16 wear lipstick when all the other girls in class do and the mother who kisses her son of 15 on the lips. The need of the adolescent to separate himself from his introjected incestuous objects and from their contemporary representatives has been aptly called "object removal" by Katan, and its accomplishment is perhaps the sure mark of maturity.

Johnson centered her attention on how particular character deviations like arson and homosexuality derive from commands issuing from the unconscious wishes of parents. Often a child or adolescent is given the choice of fulfilling the act forbidden to the parent's conscience or of losing the parent's love.

For the necessary and painful separation of adolescents from the nuclear family to occur, the adolescent has to attenuate the close tie he has to both parents. This is usually done by taking apart the parent of the same sex, often by open hostility and certainly by disenchantment with the values, attainments, and restrictions of the older generation. This sets in motion a ricochet from the parents, partly from the resentment of being challenged, partly because the adolescent rebellion coaxes from successful repression the conflicts of the parents' own adolescence. This is what makes it difficult for even the best-intentioned parents to empathize successfully with their sons and daughters.

Recent studies of families as a unit demonstrate repeatedly how the adolescent spurt forces a reshaping of family dynamics. The adolescent is the bringer of new values and new technologies. The adolescent insists on a reappraisal of the power balance within the family. The adolescent demands independence, and parents whose precarious equilibrium has been based on their total control of their children have to find new coping devices. Much pathology in parents in their thirties and forties can be difficulties in handling these problems. More frequently, however, the presenting member of the disturbed family is the disturbed adolescent—with a suicidal gesture when a

parent reacts with withdrawal, with an episode of pilfering when a mother refuses her care. These incidents must be seen in the wider context of a family coping with change.

Social Disturbances

It is insufficiently appreciated in the psychiatric literature that crucial issues are rooted in larger issues of society. Youth is characteristically a period of revolutionary ferment, which often finds expression in political, social, and asocial behavior. More recent interest has shifted to the relation between certain disjunctive groups of youngsters and these broader questions. Goodman suggested that the beat, the delinquent, and the nonconformist youth are responding, with imagination, to an adult world that fails to provide decent jobs, homes, and values into which they may grow. In the current national concern over civil rights and poverty, the much larger incidence of addiction, delinquency, and schizophrenia among the disadvantaged youth is noteworthy. On the other side of the coin, young people, both black and white, who are meaningfully engaged in effective protest have a much lower incidence of emotional disturbance.

Suggested Cross References

Psychiatric disorders that often become manifest during adolescence are discussed in this section. Further information regarding these may be found in Chapters 15 and 42 which deal, respectively, with schizophrenia and with the psychotic disorders of childhood; in Sections 26.3 and 41.6 on homosexuality and on the sexual deviations of children; and in Sections 41.4 and 41.5 on juvenile delinquency. The psychiatric treatment of adolescents is discussed in greater detail by Masterson in Section 43.7.

40.3 CHILDREN'S REACTIONS TO ILLNESS, HOSPITALIZATION, AND SURGERY

DANE G. PRUGH, M.D.

In order to consider disease states, one must also consider the state of health, now recognized as more than the absence of disease. The modern unitary view, as articulated especially by Engel, regards health and disease as phases of life. Health represents the phase of successful adaptation and, in children, of growth and development. Disease represents the phase of failure in adaptation or of breakdown in the attempt of the human organism to maintain an adaptive equilibrium or dynamic steady state; during this phase disturbances or failures may occur in the growth, development, or adjustment of the organism as a whole or of any of its systems.

Physical, Psychological, and Social Factors

Stressful stimuli of a physical, psychological, or social nature may impinge on the child to bring about a derangement of his adaptive equilibrium and the appearance of illness or a disease state. However, stress is relative, not absolute. The individual's genic endowment, his constitutional characteristics, his developmental capacities, and the nature of his past experience, including experience with disease—all contribute to his adaptive capacity. This capacity, the noxious stimuli, and the current circumstances determine the degree of stressful significance and the adaptive outcome.

In this unitary view, the organism can be said to be made up of three basic levels of organization—physiological, psychological, and social. They constitute open systems that communicate, in complex feedback operations, through the neuroendocrine system and its interrelationships with the brain and mental apparatus as well as the various organ systems. Stressful stimuli of a physical, psychological, or social nature, impinging originally on the corresponding level of organization, may produce alterations in function, bringing about feedback reverberations at other levels. Physiological and psychological defenses as well as behavioral or social adaptive devices may be called on to help maintain the adaptive equilibrium.

Depending on the child's adaptive capacity at the time of stressful experience and the nature, duration, and intensity of the stimulus, a new and more successful adaptive equilibrium may result, representing a state of physiological or psychological immunity. Conversely, temporary decompensation, chronic restriction in growth, development, or function, or serious adaptive breakdown may ensue. Many of the

symptoms or signs associated with any disease state, from fever to regressive behavior, may actually be the result of attempts by the organism to maintain adaptation or to achieve compensation, rather than the specific results of the stressful stimuli.

In designating disease states as predominantly physical or somatic or as principally psychological in character, the experienced clinician takes into account the level of organization most heavily involved in the decompensation, restriction of function, or adaptive breakdown. He recognizes that multiple etiological forces of a physical, psychological, and social nature are involved in predisposing, contributing, precipitating, and perpetuating any disease. Rather than adopting an "either-or" approach, he weighs both the somatic and the psychological components in the clinical picture and arrives at a treatment plan that takes these and the social factors into consideration.

The social field of illness includes both the effect of interpersonal forces on the child's adaptive equilibrium, with reverberations at the psychological and physiological levels, and the impact of predominantly physical illness in a child on the most important social unit—the family. A child's illness may bring about a family crisis. Families with healthy adaptive patterns may respond with behavior leading to a new and different family adaptive equilibrium, representing a type of family development. In less well balanced families, parental patterns of handling the ill child may be significantly altered because of more than usual anxiety or guilt, causing further changes in the behavior of the child or occasioning rivalrous or other responses in siblings. In seriously disturbed families, the child who falls ill may be made a scapegoat for family tensions, may be treated unrealistically as a chronic invalid, or may be handled in other ways that reflect the unconscious tendency of the parents or other family members to respond to his illness in terms of their own needs rather than his. Families from differing socio-economic and ethnic backgrounds may respond quite differently to the illness of a child and may react positively or negatively to the need for dependence on medical personnel or other helping agencies.

The importance of all these considerations renders it vital that the clinician accept the *family* rather than the individual as the essential unit for the study and treatment of disease. The illness of a child with acute or chronic disease both affects and is affected by the interpersonal family equilibrium in the particular community, society, and culture.

Some difficulty is encountered in separating the reaction to the illness or injury, representing the effects of the stressful stimuli at the physiological level, from the reaction to hospitalization or other treatment measures, representing stressful stimuli at the psychological or social level of organization.

The reactions discussed here may occur with any illness. They are largely nonspecific responses related

to the way in which the environment—parental, family, social, and physical—helps the child deal with the physical consequences and the symbolic meaning of illness or injury. Frequently, such responses can also be seen in children encountering psychological or social stresses. They are principally situational or reactive disorders, although continuing developmental deviations, structured psychoneurotic disorders, chronic personality disorders, or even psychotic disorders may be touched off or exacerbated by such stresses in biologically or experientially predisposed children. Within broad limits, however, the nature of the illness and its attendant treatment are of significant influence. This is particularly true in catastrophic or overwhelming types of illness. In such situations, there is a generic type of human organismic response related to the adaptive mechanisms involved in the handling of the phases of impact, recoil, and restitution. Such phasic response may be seen most clearly in children of school age and beyond; preschool children tend to show similar but less clear cut patterns.

With serious burns, spinal cord injuries, and respiratory polio, the phase of impact involves initial realistic fears, followed by marked regression, sweeping denial, and the use of primitive fantasy. The phase of recoil includes a lessening of regression and the appearance of depression, warded off for a time by eating disturbances or hostile, demanding behavior. The phase of restitution permits beginning adaptation to and attempts at mastery of the situation, during which individual patterns, related to premorbid personality trends, emerge.

In addition to contributory and perpetuating roles, psychological and social factors may act as predisposing and precipitating forces. Certain active children with inadequate parental supervision or with conflicts over acceptance of parental controls may be involved in frequent accidents or other self-injurious situations. Maternal deprivation may lead to failure to thrive or to delayed development, or both. Parental problems in impulse control may produce the battered child syndrome or drug intoxication of the child from repeated use of sedatives. Finally, although the mechanisms are unclear, stressful stimuli of a psychological or social nature, such as competitive pressures or the loss or threat of loss of a parental figure, seem to be involved in the precipitation of various illnesses, ranging from the common cold and tuberculosis in individuals undergoing emotional conflict to streptococcal infections in families experiencing stressful events.

Within the family equilibrium, specific reactions of parents to serious or disabling illnesses tend to parallel the phasic responses in children. Initial realistic fear is often followed, as Richmond has indicated, by: (1) a phase of denial and disbelief, persisting for weeks or, at times, months; (2) fear and frustration, associated with depression, guilt, and self-re- crimination, with intensified marital strife occurring

in some families as the parents attempt to deal with such feelings by blaming each other, the physician, or others; (3) intelligent inquiry and planning, involving the need to live with some uncertainty.

Whether a child's illness or injury produces a deleterious effect on his adaptation or the family equilibrium depends on: (1) the developmental level of the child; (2) the child's previous adaptive capacity; (3) the prior nature of the parent-child relationship; (4) the existing family equilibrium; (5) the nature of the illness or injury, including the organ system affected, the degree of prostration or pain, the type of treatment or home care, and any residual defect or handicap; and (6) the meaning of the illness to the child and his family in terms of immediately antecedent events and their actual or fantasied connection, the previous experience with such illness, the effect on the child's social, academic, and athletic capacities, and the reverberations on siblings.

Reactions to Acute Illness or Surgery

The immediate response to acute illness or injury may vary somewhat according to the organ systems affected and the corresponding reverberations at the psychological or social level. Thus, the local and systemic effects of acute rheumatic fever may have a more severe temporary impact on the psychological and social functioning of the child and produce greater anxiety in the parents than a simple green-stick fracture. Certain broad patterns of response are characteristic of children in general, with some differences related to individual variations and to developmental level.

Direct effects. Malaise, discomfort, or pain may produce listlessness, prostration, disturbances in sleep and appetite, and irritability in children, much as in adults. However, restlessness is more common in children, and hyperactivity with milder illness is frequently seen, particularly in preschool children. Anorexia and refusal of food may be marked in younger children; well meaning but anxious parents may urge food, and the child's negativistic responses often lead to feeding problems that persist long after the illness subsides. Difficulties in falling asleep, nightmares, and night terrors are common; sleeping problems also may continue as struggles for control between young children and parents.

Reactive effects. In addition to such direct effects, which may closely resemble or overlap disturbances in behavior from primarily psychological or interpersonal sources, other responses may occur.

Regression. A ubiquitous pattern in children is that of emotional or behavioral regression, seen most strikingly in older infants and preschool children but encountered also in school age children and adolescents and, for that matter, in adults to a lesser degree. In infants and young children, this regression may take the form of the reappearance of thumb sucking; return to the bottle; more demanding, clinging, nega-

tivistic, or aggressive behavior; and the temporary giving up of recently learned patterns, such as speech, walking, and bowel or bladder control. In older children, the regression occasions the reappearance of more immature social patterns, including greater dependence on the parents, particularly the mother; demanding or aggressive behavior; limitations in the capacity to share with siblings or others; and difficulties in concentration and learning. Such regression appears to stem partly from the direct effects of the illness on the child's ego and partly from the temporary falling back on earlier, more familiar modes of satisfaction or the giving up of more highly developed functions in an adaptive retreat and regrouping of forces.

Depression. Another pattern of response to illness is depression, which takes different forms in infants, children, and adolescents from those seen in adults. Depression may arise partly from the direct effects of the illness, as in infectious mononucleosis or infectious hepatitis, and partly from discouragement or restriction of activity involved, as well as the separation from the parents resulting from hospitalization. Eating and sleeping disturbances are frequent in young children as depressive equivalents, as are changes in motoric behavior from hypoactive to hyperactive. Wide mood swings often appear in older children and adolescents. Other emotional responses, often related to regressive trends, include the reemergence of primitive fears and feelings of helplessness or inadequacy. Stereotyped behavior of a compulsive or ritualized nature may be seen, as may transient hypochondriacal concerns.

Misinterpretation. Misinterpretation of the meaning of illness or injury is a common phenomenon. It is related to the child's limited capacity for intellectual understanding and testing of reality and his tendency toward magical or animistic thinking, particularly in the young child. Younger preschool children ordinarily view pain or discomfort arising from illness or accident as punishment for real or imaginary transgressions. Older preschool and early school age children show fears of bodily mutilation related to treatment procedures. Such fears are more intense when sensitive areas, such as the head or the genital organs, are involved; fears of harm to the genital organs are related to sexual differentiation and psychosexual development.

Physiological concomitants of anxiety. Psychological conflicts about the meaning of illness, enhanced by regressive trends, may result in the appearance of the physiological concomitants of anxiety. Tachycardia, palpitation, hyperventilation, diarrhea, or other signs and symptoms may be exhibited. Such physiological changes, ordinarily reversible, may compound the effects of the predominantly physical illness, as in the deleterious effects on diminished cardiac function in congestive failure or the perpetuation of diarrhea originally arising from bacterial infection or parasitic infestation.

Conversion reactions. Other psychological reactions seen frequently in school age children or adolescents in relation to physical illness include conversion reactions. These disturbances affect the voluntarily innervated striated musculature and the somatosensory apparatus, with their unconsciously symbolic expression of emotional conflict. They are to be distinguished from psychophysiological disorders, which affect involuntarily innervated systems and visceral end organs, without symbolic significance.

Conversion disorders are manifested in a variety of personality pictures, ranging from the relatively normal child to the classical hysterical personality. Transient, mild to moderate symptoms of this nature are frequently encountered during convalescence from a predominantly physical illness. Such an illness may temporarily block a child's intense developmental need to achieve scholastically, athletically, or socially. Or the illness may precipitate conflict between a regressive wish to continue to be cared for by the mother and guilt over such wishes as the result of the pressure to return to the competitive arena. Frequently, the symptoms of the physical illness are unconsciously incorporated into the conversion symptomatology, as in the continuance of pain, vomiting, headache, and dysphonia or, in a more general sense, weakness and easy fatigability. At times, other symptoms, such as certain types of syncope or disturbances in gait, may appear. Many of these conversion reactions are resolved in a few days or weeks, but they may persist chronically in a child with limited adaptive capacity or one whose family encounters special difficulty with the convalescent phase of the illness.

Dissociative reactions. Dissociative reactions, such as amnesia or pseudodelirious states, may also occur. These may compound or be compounded by the actual delirium, which is often of a subclinical nature. In children, delirium may arise in response to drug administration, or it may accompany systemic diseases with marked fever, even in the absence of any direct insult to the central nervous system. Catatonic behavior without the significance of psychosis may be seen temporarily in normal or mildly disturbed children if the physical, psychological, or social circumstances are sufficiently stressful.

Perceptual-motor lags. Other direct and indirect effects on behavior may be manifest in the convalescent phase. Meyer and Crothers have described children who have exhibited lags in perceptual-motor functions following systemic illness, such as pneumonia. The lags may persist for several weeks or months without apparent damage to the central nervous system. Such children, who may have experienced a temporary disturbance in cerebral metabolism—often with delirium, compounded by regressive tendencies—may exhibit learning difficulties after returning to school. These difficulties may become chronic, resulting in resistance to learning or other behavioral

disturbance if they are not recognized so that the parents and teacher can help the child return gradually to full academic performance.

Reactions to Chronic Illness or Handicap

Many of the considerations mentioned for acute illnesses and injuries are applicable to chronic illness and handicapping injury. Although serious repercussions on the child's personality development and family functioning are frequent, many children with chronic disease or with congenital or acquired handicaps make a surprisingly adequate adaptation to or compensation for their disabilities. Those variables relating to the child's previous adaptive capacity and the parent-child-family balance appear to be of more importance than the nature of the specific disease or handicap.

Special challenges to development do exist for children with blindness or deafness, with some differences in responses to congenital versus acquired defects. Problems in sexual development are present for children with pseudohermaphroditism or extrophy of the bladder. Difficulties in adaptation arise for the child whose movements are restrained in an orthopedic cast and for the handicapped child who requires special prosthetic devices. The debilitation and discomfort produced by certain diseases certainly have an effect on the child's social or academic functioning and on the parents' responses. Different children and parents may respond differently to such situations, however. The concept of specific personality malformations resulting from particular diseases or handicaps has been largely abandoned. Even a small and virtually unnoticeable defect may carry overwhelming significance in certain families for unconsciously over-determined reasons. Although visible cosmetic defects may be most troubling in some families, in others a hidden metabolic defect may be more mysterious and threatening, without relation to its actual severity.

Effects on personality. The personality pictures seen in children with various diseases or handicaps appear to fall along a continuum, ranging from over-dependent, overanxious, and passive or withdrawn patterns—with strong secondary gains from illness—to overindependent, aggressive modes of behavior—with strong associated tendencies to deny illness, even to markedly unhealthy extremes. A middle group of children show realistic dependence and acceptance of their limitations, with adequate social patterns and compensatory outlets and with no more denial than is consistent with the maintenance of hope.

Parental reactions also fall along a continuum, ranging from overanxiety, overprotectiveness, and overindulgence—often with difficulties in setting limits on the child's demands—to problems in acceptance of the child's disability—frequently with denial of its extent, projection of guilt onto the medical staff, reluctance to accept recommended treatment, and occasional rejection or isolation of the child within

the family unit. A middle group of parents can, after the initial phases of response, accept comfortably the child's limitations, permit him appropriate dependency, and help him exploit constructively his capacities and strengths.

Little correlation appears to exist between extremes of unhealthy parental and family response and specific types of personality distortion on the part of the child. Chronic personality disorders of overdependent, inhibited, aggressive, or pseudoindependent patterns occur commonly in such situations, but such disorders may also be seen in children without physical disability. Conversion mechanisms or other psychological reactions may lead to invalidism in slightly handicapped children. Marked depression and hopelessness have been observed by experienced clinicians to affect detrimentally the course of chronic diseases, such as leukemia.

Effects on body image. Difficulties in the establishment or maintenance of the body image are present for most children with a chronic illness or handicap, but they may also be seen in children without physical disfigurement. Size, strength, and attractiveness do play some role in the child's confidence and social adjustment, but only in very severe cases or in individual family situations do these factors appear to be of the utmost importance. In adolescents, who need acceptance by the peer group, reactions to a damaged body image may interfere with rehabilitative procedures.

Reactions to treatment. Although most children with chronic diseases or handicaps respond positively to the effect of recent drugs and surgical procedures, a small group may show paradoxical responses, with psychological decompensation, conversion, and other symptomatic reactions. In an unhealthy family situation in which the child's role as an invalid has become central, the precipitation into health of the child by the treatment may upset the tenuous balance of adaptive forces, making it difficult for the child to return quickly to a healthy role within the family and outside.

In adolescents, as in adults, psychotic reactions occasionally develop in response to adrenocorticotrophic hormone or cortisone during treatment for rheumatic fever or other diseases. In addition to the direct effect of the drug on the brain, problems in realignment of intrapsychic and interpersonal balance may also be involved.

Reactions to Hospitalization

Hospitalization, with its separation from home and family and various treatment procedures, may cause reactions in a child according to his development.

Short term hospitalization. Most, if not all, infants and children show some reaction to the experience of hospitalization. Infants in the 1st half year of life exhibit temporary and rather global responses, arising from different methods of feeding and han-

dling. Infants in the latter part of the 1st year experience stranger anxiety and separation anxiety, often with some regression and depression.

Children under 4 years of age are most vulnerable to separation from the mother. This separation is often interpreted as punishment or desertion, resulting in feelings of helplessness or fears of attack related to the child's limited capacities for reality testing. In addition to regression and various symptomatic reactions, the phasic sequence of protest, despair, and detachment—the last often associated with withdrawal and depression, as described by Robertson—is frequently seen after a few days of hospitalization, even in well adjusted children, and may be troubling to parents.

For the child from 4 years through the early school age period, the psychological meaning of the illness and its treatment appear to have greater potential effects than the actual separation from the parents. Fears of bodily mutilation and the tendency to misinterpret painful treatment procedures as punishment often invoke anxiety, regression, and the other manifestations mentioned earlier; boys ordinarily exhibit more aggressive responses than girls do.

Older school age children, who can comprehend the reality of the experience more fully, may show mild regression and anxiety over the functioning of certain organs, related to incomplete body images. Fears of genital inadequacy, muscular weakness, and loss of body control or mastery contribute to the feelings of anxiety and inferiority characteristic of this stage. In adolescents, many of the same trends are seen in more muted fashion. There are also struggles to establish a sense of identity and independence, which sometimes interfere with the teen-ager's cooperation in treatment programs.

Parental reactions show some similarity to the patterns seen during acute illness. Denial and disbelief is less marked with less serious illness, with significant exceptions. Many parents fear criticism from the hospital staff regarding their role in the illness or their effectiveness as parents. Some may show strong rivalry with nurses or physicians, interpreting professional competence in handling the child as a threat to their own parental capacities. Feeling left out or unwanted is also common among parents. A few may project their own guilt onto the hospital staff and blame them for minor difficulties. Difficulty in accepting recommended treatment occasionally leads to their signing out the child against advice.

Posthospitalization reactions may occur, even in children who have been able to maintain control throughout the hospital experience. Regressive tendencies, outbursts of anxiety, and fears of doctors or needles may appear in children after they return home. When parents are unprepared for such behavior, overprotective or overrestrictive tendencies may cause significant interpersonal reverberations within the family unit.

Although some reactions of the types described are virtually universal, the majority of children are able to adapt successfully to the experience of hospitalization, showing self-limited reactions that ordinarily subside after several weeks to several months. But the possibility of emotionally traumatic reactions is great enough, particularly in preschool children and in previously disturbed children, to require careful thought about the indications for hospitalization and to warrant the use of psychological preventive measures.

Long term hospitalization. With modern treatment measures, long term hospitalization or institutionalization is rarely necessary for the chronically ill or handicapped child. The studies of Bakwin and Bowlby, in particular, have indicated the likelihood of serious emotional deprivation for such children. In large institutions, especially, children exhibit chronic depression and detachment, often leading to shallow social relationships, distorted time concepts, limited capacities for learning, lowered resistance to disease, and rebellious or antisocial behavior. A few children, because of specially appealing qualities, can reach out to the often limited staff in such settings to meet their emotional needs, but significant personality distortions have resulted for many from such hospitalization.

Reactions to Surgery

Many of the observations on hospitalization are pertinent to surgical experience for the child. Special problems may arise in regard to operations with necessarily mutilating effects, such as amputation. If a young child misinterprets the procedure as punishment or a hostile act, he may, as with certain other procedures, become aggressive in fantasied self-defense: fear, withdrawing, or other types of behavior may result. Phantom limb phenomena, as seen in adults, are rare in children; but strenuous denial may lead to difficulties with prosthetic devices. In older children and adolescents, particularly those with hysterical personality structures, an unconscious need to suffer, arising from guilt over hostile or sexual feelings, may produce recurrent pain.

Anesthesia may evoke fears of loss of self-control. And older children may have fantasies about what might be done under narcosis to various bodily organs. Children of differing developmental levels respond differently to preoperative sedation; preschool children are often stimulated rather than sedated by certain barbiturates. Marked anxiety over operative procedures may significantly raise the sedation or anesthetic threshold, at the same time reducing the margin of safety in patients with serious heart disease or other debilitating conditions.

Treatment and Preventions

In the management of physically ill children, the physician can himself offer effective help of

a supportive and preventive nature to child and parents. In addition, he has the responsibility to act as the coordinator and integrator of the diagnostic, therapeutic, preventive, rehabilitative, and educational skills of many medical subspecialties and numerous other highly trained professional persons available to the child and his family in hospital and community. In so doing, he must draw on the principles of continuity, communication, consultation, collaboration, and coordination in order to render such help most effective to the child patient and his family.

Treatment and prevention of unhealthy psychological reactions to illness or injury begin with the diagnosis and are importantly involved in the interpretation of diagnostic findings and treatment recommendations to the parents. Anxious, confused parents need careful explanations and opportunities to ask repeated questions and to air their misconceptions. The physician also must avoid critical, judgmental attitudes toward the parents, and he should minimize their guilt and self-recrimination.

Acute illness or injury. When a child has an acute illness or injury, the physician should carefully explain each procedure in advance to him, using terms and concepts appropriate to his developmental level. Preparing the young child for elective hospitalization for tonsillectomy, for example, involves a brief discussion of the concrete details of the hospital routines and anesthetic procedures and a truthful statement that his throat will be sore afterward. Ideally, the parents should be prepared in order to prepare the child. For the preschool child, his mother's overnight stay in the hospital with him is the most valuable preventive and supportive measure. For the older child, daily visiting is important, whatever his illness.

Special recreational programs in the hospital, permitting the child to play out his anxieties before and after treatment procedure, have real value. Also valuable is schooling, available on a flexible basis even to the briefly hospitalized child. The combined observations of the physician, nurse, recreational or occupational therapist, teacher, and other personnel on a hospital ward have great diagnostic value.

Children should be cared for at home whenever possible, and due thought should be given to the contraindications as well as the indications for hospitalization. When hospitalization is indicated, every effort should be made to cooperate with the parents in a therapeutic alliance, and their concerns and needs, as well as the child's, should be kept in mind during hospitalization. If such an approach is adopted, most parents can make vital contributions to the hospital program through their participation in the care of their own—or at times other parents'—children. The handling of crucial phases in convalescence should be worked out cooperatively with parents. Explanations of regressive or other posthospitalization behavior should be given in advance so that they will see this

as a characteristic of childhood and not as a personal failure.

Chronic illness or handicap. For children with chronic illnesses or handicaps, a variety of treatment measures apply. The use of a supportive psychotherapeutic relationship with child and parents underlies all other therapeutic steps. Without such a positive relationship, other treatment is less than optimally effective. The physician should call on the skills of other members of the rehabilitation team, including the child psychiatrist, the psychologist, hospital nurses, social workers, school teacher, recreational and occupational therapists, public health nurse, and other professional persons in the hospital and the community. In the hospital, a social group worker can be effective with groups of chronically ill or handicapped children. Group discussions among parents of children with particular kinds of disabilities are also helpful.

The chronically ill or handicapped child should be cared for in the home whenever possible. Sometimes he can be handled in a regular class in school, with the addition of special classes where necessary. If placement in an institution is necessary, the smaller institutions or group foster homes with medical and nursing facilities are best.

For the chronically ill child undergoing surgery, the principles already mentioned are vital. With a very young or seriously disturbed child, special arrangements to have the mother in the child's room when he undergoes preoperative sedation and to have her there when he awakens can afford continuity for the child. This may also avoid confused battles on the way to the operating room. Opportunities to ask questions after as well as before such procedures can help children work through their misconceptions and anxieties.

Although ill children need some rest and quiet, their natural tendencies toward activity and the hyperactivity engendered by illness and by restriction of activity should be taken into account. In the hospital, a regimen of moderate activity is helpful. Advice about absorbing but quiet activities can be most constructive for the potentially harassed and anxious mother taking care of the child at home. Such an approach can minimize struggles over inappropriately enforced bed rest, which can spread into other behavioral areas and stimulate hyperactivity of a physically and psychologically detrimental nature.

Terminal Illness

The child's concept of death is not fully developed, in the sense of realistic comprehension, until he is about 10 years old. Therefore, children can quite adequately deny fears of death, but show other, more immediate, fears of pain or treatment. Even in adolescents, fears of death are often expressed in terms of fear of pain or of need for someone to be with them to help them in difficult moments. Parents may carry out mourning in advance, sometimes seeming somewhat

detached from the child at the end, but then reexperience depression or guilt after the child's death. Physicians are often disturbed by their own feelings during the child's terminal illness. The important thing is for the child and parents to have someone to whom they can express their feelings, rather than maintain an unrealistic silence. Psychiatric consultation may be helpful in understanding such situations and in working out a plan for supportive help. Parents often require support after the child's death, and opportunities for this should be routinely available to them.

Suggested Cross References

More information regarding the effects of separation from the mother may be found in Yarrow's section on maternal deprivation (Section 44.1). Children's reactions to dental disorders and treatment are discussed by Ewen in Section 31.4. Section 28.1 contains further information regarding psychological reactions to gross stress, and Sections 31.2 and 31.3 discuss adult reactions to medical and surgical illness and treatment.

Special Symptom Reactions

40.4 LANGUAGE DISTURBANCES

KATRINA DE HIRSCH, F.C.S.T., LSc.

Language in its different forms—spoken, written, and printed—is a system of communication among human beings who comprehend and use symbols possessing arbitrary meanings, according to the rules established by a given community. Impairment of language, then, consists of partial or total failure to comprehend or use such symbols for effective communication.

In every case of a language dysfunction, a variety of interrelated factors are operating. To begin with, there is the young organism with its constitutional strengths and weaknesses, and there are reasons for believing that linguistic endowment varies in different individuals. There are the adjustments that the organism makes to its constitutional or acquired deficit and the defenses that it develops, which determine much of its functioning. There is, finally, the emotional climate in which it makes this adjustment, which, in turn, modifies the organism's response to its original difficulty. None of these can be viewed in isolation; each language dysfunction has to be evaluated within the framework of all three.

This presentation does not discuss voice disorders or communicative difficulties related to the instrumentalities of language (sensory deficits as in loss of hearing), structural defects (as in cleft palate), or neurological disorders interfering with the peripheral speech mechanisms (as in dysarthria). The following discussion is limited to noninstrumental aspects of language disturbances.

Disorders

Aphasia. In the acquired aphasia of adults (defined by Schuell et al. as a generalized language deficit that crosses all modalities and that may or

may not be complicated by other sequelae of brain damage), both decoding and encoding processes are disordered in varying degrees. Acquired aphasia in children is rare. If it occurs in association with infectious processes, it usually results in only a temporary lowering of functional competence and is frequently, therefore, a transient symptom.

The term "congenital aphasia" has been used to describe failure to develop language due to demonstrable central nervous system impairment and not related to limitations in intellectual potential, sensory deficit, or severe psychopathology. However, not all children at relatively advanced ages who are unable to comprehend or use symbols have a verifiable history of brain injury or show positive signs on the classical neurological examination or the electroencephalogram. Some of them present "soft" neurological signs and are thus suspected of minimal brain injury; this would be an inferential diagnosis and one for which the criteria differ from one clinical setting to another.

Orton coined the term "developmental word deafness" for children who show severe difficulties in language reception and expression along with a markedly positive family history of language disability. He felt, as does Bender, that this syndrome belongs in the category of developmental language and learning disturbances. Since investigation of the linguistic dysfunction itself does not necessarily permit deductions as to etiology, it may be preferable to use a descriptive term, such as "communicative disorder of early childhood," which implies a continuum of language deficits, rather than a label like "aphasia," which has etiological connotations.

Clinical characteristics. The features of early, severe communicative difficulties in children are profound inattention to auditory and specifically to verbal stimuli and inability to assign symbolic significance to input events. Children with such difficulties hear, but they do not necessarily apprehend. They have trouble with what Hardy calls "auding"—that is, with perceiving, processing, storing, and re-

calling the serial order of information received through auditory pathways. Their auditory memory spans are short, and their auditory discrimination defective. In such children, the perceptual field seems to be unstable, and they have trouble separating the auditory figure from the background of irrelevant stimuli.

The degree of expressive impairment varies and is usually secondary to the receptive deficit. Speech, if it is present at all, mirrors the diffuse reception: it may be severely limited in quantity and primitive and undifferentiated in quality. Echolalic responses or jargon may be substituted for meaningful communication.

During the past 15 years attention has been drawn to the fact that children with early communicative disorders frequently show pervasive deviations in non-linguistic areas: primitive postural reflexes, global motility patterning, dyspraxic features, defects in body image, crude visuomotor responses, and, among behavioral signs, impulsiveness, distractibility, hyperkinesis, and response variability.

In these children, the absence of serviceable language tools tends to interfere with developing ego functions of mastery, impulse control, and the ability to postpone gratification. The fact that they are unable to discharge tension by way of words, that they cannot verbally express anger and aggression, often results in severe emotional problems. The intensity of psychological disturbance depends not only on the degree of impairment, but also on the ability of the environment to tolerate and support this kind of child, whose difficulties with control may be severe and whose infantile needs are often far greater than those of others. Eventually, and with the help of appropriate therapy, a number of such children do learn to use words, although paucity of verbal output, primitivity of sentence construction, and learning disabilities usually follow in the wake of severe retardation in the acquisition of language.

Dyslalia. The early language development of dyslalic children, who between the ages of 4 and 7 have difficulty in making themselves understood, is often somewhat delayed. Their severe articulatory difficulties; their inability to pattern phonemic detail, as described by Masland and Case; their tendency to omission, substitution, and distortion of sounds; their telescoping of words—all tend to obscure more subtle receptive language deficits: short auditory memory span, diffuse auditory discrimination, trouble with the sequential ordering of incoming information. While dyslalic children grossly understand language of others, they may be unable to interpret the small, grammatical words that represent spatial, causal, and temporal relationships.

It is essential to make a distinction between articulatory difficulties per se and disorders of a primarily linguistic nature. A child may, for instance, correctly produce an "F" or a "V" in isolation yet confuse the two sounds in the pluralization of nouns.

The dyslalic child may have trouble evoking words, he may have difficulties with syntax, and he may fail to incorporate basic morphophonological rules. Intelligibility often fluctuates; it decreases with the length of units and the complexity of content, and verbal communication sometimes breaks down completely when the child has to cope with intricate syntactical structures and the organizational load thus becomes too heavy.

The dyslalic child's infantile sound substitutions and his occasionally primitive sentence construction may suggest regressive modes of functioning. It is true that a number of such children are as immature psychologically as they are physiologically. Some find it hard, for instance, to give up lisping, which is often a residual of dyslalia. Secondary emotional problems, moreover, tend to arise as the result of difficulties with expression and communication. As dyslalic children mature, their speech generally improves. However, subtle articulatory immaturities and residual problems with formulation and organization of language can be observed at later ages.

Cluttering. Cluttering, like dyslalia, is one of the constitutionally determined linguistic disturbances, and severe difficulties with the organization of language often persist into adulthood. The syndrome was first described by Weiss in the early 1930's. Cluttered speech is characterized by excessive rate, fluctuations in rhythm, monotony, frequent repetitions of syllables and sounds, articulatory instability, and a tendency to reverse the order of sounds and words. On the receptive side, one finds disorders of auditory attention, severely deficient auditory discrimination, and sometimes diminished psychoacoustic ability.

Specific reading and spelling disabilities. A significant number of clutterers are found among children with severe reading and, above all, spelling disabilities. These difficulties, like the communicative disorders of early childhood, may occur as the result of encephalopathies. The term "specific dyslexia" is best reserved for cases which present demonstrable evidence of central nervous system dysfunction. However, not all children suffering from reading disabilities have positive signs on the classical neurological examination and/or the electroencephalogram or have verifiable histories of brain injury. Severe reading and spelling disorders frequently occur in given families and are thus assumed to be genetically determined. Such difficulties are primary only when not related to psychopathology, limited intellectual endowment, or extraneous factors (such as illness, poor teaching, frequent changes of school, or deprived environmental conditions) and when the child's performance in reading and spelling is substantially below his achievement in other academic subjects and not commensurate with his intellectual potential.

Clinical characteristics. Like children with massive oral-language deficits, subjects with severe reading and spelling disabilities show a fluid, diffuse mode

of perceptuomotor organization. Their responses in most areas of functioning may reflect a maturational lag, sometimes so severe that it seems to be rooted in the very biological matrix. Bright and highly motivated children whose self-image has not been damaged as a result of early failure may, with the help of contextual clues, compensate spontaneously for their early perceptual fluidity and, after an initially slow start, do well in reading. In more severe cases, however, intensive and long term remedial reading therapy is indicated. With such help, the large majority become fairly adequate, if not fast, readers. In extreme cases, the goal is only functional reading.

In cases of severe spelling disabilities, remedial help is a necessity; however, it is usually of limited effectiveness, and a large number of children remain poor spellers. Spelling requires ability to reproduce not only the over-all gestalt of the word but also its precise internal design. Children who are suffering from severe language disturbances are unable to maintain a linguistic gestalt. This is clearly evident in poor spellers: although they may remember the way a word looks when it is printed in bold black letters on a white card since the figure clearly stands out from the ground, they are likely to lose the configuration when required to reproduce the same word in context. Poor spellers perceive words as only vaguely structured wholes; on the way from perception to graphic representation, they lose important gestalt attributes, so that the end product usually bears little or no resemblance to the correct pattern (de Hirsch). For these individuals, words have no physiognomy and never become familiar.

Severe spelling disorders are often complicated by writing disabilities; added to the children's basic trouble with the formulation and organization of content, this results in overwhelming difficulties with written composition. These children's jerky dysrhythmic handwriting mirrors their dysrhythmic speech. Their compositions, characterized by omission of sounds and words and the telescoping of long configurations, reflects their cluttered, disorganized verbal output. Nearly all clutterers are poor spellers; both show striking difficulties with auditory discrimination.

Stuttering. Stuttering is closely related to cluttering, but physiological signs, as they have been discussed in the case of other language disturbances, are often absent. Weiss considers stuttering to be a neurotic manifestation, superimposed, in many cases, on cluttered, disorganized speech.

Stuttering is a highly controversial subject. Earlier researchers related it to neurological dysfunction. Froeschels, who has contributed an excellent description of the evolution of the syndrome, calls it an aphasic-like disorder. The psychoanalytical school is impressed with the significance of early oral- and anal-sadistic features. Johnson, whose theories have been widely accepted in America, maintains that stuttering is a semantogenic disturbance and results from

the erroneous labeling of early nonfluency as stuttering. The position taken here is a modification of Wyatt's.

Stuttering in young children well illustrates the complex, dynamic interrelationships among the neurophysiological, linguistic, and affective aspects that are typical for all language dysfunctions. Stuttering is usually first noted between the ages of 2 and 4, when the child has to struggle with complex grammatical forms and, in the short span of 18 months, passes from a primitive to a highly integrated form of language organization. At that age his neurophysiological maturation may lag far behind his emotional and intellectual need to express relatively complex and differentiated content. This happens at the time in the child's life when he has to renounce early instinctual gratifications, when aggressive impulses are being discouraged, when a new sibling often threatens his place in the family, and when, finally, in one way or another, his ties to his mother are being loosened. When the two crises—the neurophysiological-linguistic and the emotional—coincide, stuttering may first become apparent. Primary stuttering—with its easy, effortless repetition of syllables, sounds, and words—disappears as the child's neurophysiological maturation enables him to cope with a heavy linguistic load, provided there are no valid psychological reasons for the perpetuation of the symptom. In older subjects, however, stuttering—with its severe blocking, tension, and avoidance rituals—has very different implications. In most cases it becomes part of the ego's defensive system; it is rarely amenable to treatment by the speech therapist and should be regarded as a psychiatric disorder.

Differential Diagnosis

It is essential to distinguish between emotional difficulties that are secondary to language deficits and those primary psychological disturbances that are at the very core of some communicative and learning disorders. The dividing line is not always sharp. An intelligent boy, for instance, who has consistently failed in reading and spelling may show phobic attitudes that complicate and obscure his original language problem. Such a boy's ability to invest effort in a subject like science suggests that his phobic response to reading may be a reaction to his specific weakness in the language area. However the learning difficulties of children whose failures extend to all areas of functioning have psychiatric implications—all learning experience remains meaningless and fragmented. Such children may be so involved in fantasies that, as Pearson and de Hirsch have pointed out, they have no psychic energy available for academic requirements; their difficulties are usually related to ego impairment, and prognosis tends to be poor.

The differential diagnosis between specific language disorders and psychiatrically determined ones

may present considerable difficulties. Severely limited speech output, fluid perceptual experiences, defects in body image, and often overwhelming anxiety are characteristic both of schizophrenic children and of those suffering from early and severe communicative disorders. Bender maintains that in both groups one is dealing with a delay in neurological integration and with the persistence of infantile neural patterning. In schizophrenic children, however, fluidity is pervasive and involves the total personality organization, including the establishing of ego boundaries; in children with specific language deficits, on the other hand, instability seems to be confined to the perceptual motor and linguistic realm.

Psychotic Language

The formal testing of the language reception of psychotic children is difficult because they are hard to reach, they are usually more responsive to stimuli from within than from outside the organism, and they perceive the world in very primitive organizational schemes. Hoberman and Goldfarb's experiments have shown that auditory discrimination of psychotic children is defective, and it can be assumed that their feedback experiences are diffuse and unstable.

The bizarre and idiosyncratic character of the verbal output of psychotic children has received considerable attention. A number of striking features can be observed in their verbalizations. The first of these is the often total absence of communicative intent. Communication requires a complicity between partners, as it were, and psychotic children are not in on this arrangement. Language, as it is used by normal individuals, has to be consensually validated; it is, among other things, an instrument of interpersonal behavior. The failure of psychotic children to establish stable object relationships is reflected in their echolalic speech, with its mechanical, birdlike quality which has a very different flavor from the occasional echolalic utterances of children with severe communicative disorders. The latter may echo words, but they do so for purposes of clarification, to try out words for size, as it were. Pitch and inflection, which carry the emotional and communicative as opposed to the conceptual load, are usually normal. In psychotic children, sentence melody and pitch are inappropriate.

In schizophrenics, as Freud pointed out, words are no longer referents but instead become the things themselves and, as such, acquire magic properties. Werner and Kaplan spoke of a "thinglike" handling of linguistic forms. As described by Laffal, words in such subjects do not necessarily refer to communal experience, nor do they follow established sets of conventions. As in dreams, words may be distorted or telescoped; a whole train of thought may be condensed into a single word. Language in psychotic children is not necessarily in the service of ego and reality; it more often expresses primary processes. A schizophrenic boy, for instance, will say, "There is

no use learning to read the letter K; it is not sympathetic; it has too many spikes." For this boy, the letter has not acquired objective conventional significance but is experienced in terms of primary processes. In this instance, it reflects his primitive fears of aggression and retaliation.

Some children are, of course, damaged on several levels of integration. There are autistic children who are clearly brain-injured; their dysfunctions are apparent in both physiological and psychological aspects of functioning. In some learning disabilities that appear to be related to psychopathology, neurological examination points to diffuse organicity. Some children with specific language difficulties show signs of withdrawal which are secondary to their communicative disabilities. A prolonged diagnostic investigation is sometimes required to determine the relative contribution of affective, neurological, and sociological aspects of communicative failure.

Suggested Cross References

Language disorders may occur as separate entities, or they may occur in the context of other clinical pictures. For more detailed discussions of these, see the sections on developmental disturbances and reactive disorders (Section 40.1), childhood psychoneurosis (Section 41.1), psychosis (Section 42.1), organic brain disorder (Section 42.3), and mental retardation (Section 22.1).

40.5 ENURESIS

CHESTER M. PIERCE, M.D.

From antiquity, physicians in a diversity of civilizations have been baffled by the problem of enuresis. As is always the case when doctors are perplexed, one can find catalogues of the most astonishing treatment techniques, since the physician makes valiant efforts to master the problem by means of empirical approaches. As late as the time of Pliny, there were prescriptions to eradicate enuresis by means of consumption of wood lice or swine's urine. In the first pediatric textbook, which appeared during the Renaissance, enuresis was discussed. However, even in the 19th century, many an enuretic received prescriptions not unlike those which Pliny listed. Today there is still a plethora of treatment approaches for enuresis, with enthusiastic claims and counterclaims for all, proving only that the ancient problem of enuresis is still unsolved.

Definition

Officially, enuresis is classified as a habit disturbance under the special symptom reactions. Thus, it is regarded as a transient reaction, manifesting itself primarily as a habit with repetitive symptoms, the inappropriate and involuntary passage of urine.

Operationally, enuresis can be defined as bed wetting or clothes wetting in persons over the age of 3 who fail to inhibit the reflex to pass urine when the impulse is felt during waking hours and those who do not rouse from sleep of their own accord when the process is occurring during the sleeping state.

Epidemiology

The chronological antiquity of enuresis is matched by its geographical ubiquity. No country and no class of citizen in any country seem to be totally exempt from enuresis. Enuresis is found in the developing nations as well as in highly developed countries. The disorder seems to be more prevalent in socioculturally disadvantaged individuals. For this reason, one finds a greater proportion of enuretic Negro youngsters and youngsters who make low scores on psychometric testing.

Enuresis occurs twice as frequently in males as it

does in females. The reason for this ratio is thought to be the result of such factors as increased effort by the girls and their mothers to banish the habit, easier submission to training by young females, etc.

At present it seems that enuresis occurs with greater frequency in combination with one or more of the following disturbances: (1) passive-aggressive or passive-dependent reactions; (2) sleep-walking; (3) delinquency; (4) inferior dentition (as measured by decayed, filled, or missing index); (5) chronic genitourinary tract complaints (urgency, frequency, nocturia, precipitancy); (6) speech disorders. A family history of enuresis is related to enuresis in most studies. In addition, a statistically significant number of adult enuretics give a family history of sleep-walking, as compared with the lower incidence of sleep-walking history given by the patients used as controls in the study.

Eighty-eight per cent of children have ceased enuresis by age 4½. By age 7½ about 93 per cent of all children are dry. Of the remaining 7 per cent, almost all have ceased wetting by age 17. Yet the magnitude of the frequency of the symptomatic habit is seen from an abundance of military statistics, which indicate that between ½ and 2 per cent of all who enter the service are enuretic. Even allowing for the youth who wets to escape his enlistment, there can be no doubt that there are a significant number of adults in the general population, probably more than 1 in 100, who have a problem of wetting the bed at least several times a month.

Etiology

Both investigators and practitioners view the etiology of enuresis as due to contributory components of an organic, intrapsychic, or social nature. In some cases one of these components may be the total cause; in other cases, two or three reasons are intertwined.

Organic causes. In about 10 per cent of cases of enuresis, an organic defect involving the genitourinary tract can be located. When there is only nocturnal enuresis, the likelihood of organic etiology is small. The combination of nocturnal and diurnal enuresis, especially in a patient with frequency and urgency, is highly suggestive of an organic basis for the complaint.

Some of the genitourinary tract causes of enuresis are genitourinary infections, trigoneurethritis, vulvitis in girls, meatal stenosis in boys, and anomalies of the posterior urethra and urethral valves. Phimosis is rarely a cause of enuresis.

The family history of enuresis found in enuretics has suggested that a gene may be influential in determining enuresis. This theory is hard to prove or disprove. It is striking, however, that many persons cease to wet at about age 20, at the same age as some of their blood relatives did. It is suggested that the enuretic may inherit a slowly maturing neural apparatus and that, as a result of this inheritance, he

does not sense bladder fullness or cannot act on the signal if it is received. Since enuretic children and adults are much more likely than the control subjects to have abnormal brain wave patterns, further research may show a central nervous system relationship to enuresis.

Another hypothesis on the connection of the nervous system with enuresis is that dryness is a result of self-acquired control over the levator ani muscles to inhibit the micturition reflex and thereby increase the bladder capacity. To micturate, one willfully contracts the abdominal muscles and relaxes the levator ani. Enuresis is seen as a failure in attaining bladder enlargement. Another theory is that since bladder distention is a stimulus for micturition during sleep, the incidence of deep sleep or hypersomnolence by enuretics may be related to enuresis.

Social factors. Numerous social factors are probably of importance in enuresis. Some authorities interpret the family history data as indicating that the parents may be permissive and unperturbed by enuresis. They, therefore, allow it to continue for longer periods of time. The enuretic may have failed to get proper and consistent training in the habit of dryness. There may be some significance in living in a cold house and not wishing to get up to go to the bathroom or in not having convenient bathroom facilities. Since the enuretic uses his symptoms to express aggression and hostility and to get attention, enuresis may be a manifestation and a reflection of psychopathology in a family.

In enuretic boys there is often found a mother-son relationship in which the child continues his enuresis because of the unconscious expectations and wishes of the mother. The mother often has depreciatory attitudes toward males that make her demand that her son be both ineffective and rebellious. Since the child comes to fear women as dangerous and disappointing if he is active in the male role, he adopts a passive attitude and avoids the masculinity that would both threaten and displease the mother. The development of a passive-aggressive personality and the use of enuresis as a symptom serve the needs of both mother and son. That is, the son maintains worth to the mother because he is not growing to true masculine maturity. The family constellation is such that the father also rewards the son because the boy does not constitute a threat to the father. Not surprisingly, therefore, a young adult male who still wets the bed is found to view his home as an idyllic place, despite what he regards as excessive bickerings between his parents, often over issues of the mother's seductiveness. This young adult seems to prefer to be a Peter Pan who does not have to assume grown-up responsibility.

Female enuretics, on the other hand, have a very strong attachment to their fathers. Just as the male enuretic may be a mother's boy, the female enuretic may be a father's girl. Unlike her male counterpart,

however, the female is found to be a leader of her peers in social and scholastic achievements and interests. Theoretically, the female enuretic may resort to bed wetting as a means of reducing penis envy problems, which are prominent in these subjects.

Pathophysiology

Recent investigations have considered the enuretic process as a sleep disturbance. Research has been conducted by having enuretics and control subjects sleep in laboratories equipped to record such data as the moment of bed wetting, the changes in heart rate, perspiration, respiration, and muscle tension. The dreams of the enuretic have been recovered by awakening the subject while he is dreaming. This material has been correlated with bladder volume changes through the night and the ability of an enuretic to sleep through a measured amount of noise.

When the enuretic is compared with control subjects, he seems to have different physiological responses. The enuretic child sleeps very soundly. During enuresis, there may be tachypnea, tachycardia, and compensatory bradycardia. The enuretic boy frequently has an erection during micturition. On the nights that he wets, an enuretic child often dreams of hostile and aggressive actions, such as witnessing a gun fight, an accident, or a fire. The young adult, however, on the nights that he wets, dreams of dependent activities, such as a mother preparing a feast or a joyous reunion with a loved one.

Clinical Description

The observation of clothes wetting or bed wetting is made very easily. However, the observer cannot tell whether there is deliberate wetting for some secondary gain; whether there is an organic etiology, as in neurogenic bladder or spina bifida defects; or whether the individual is enuretic. Usually the person who brings the chief complaint can offer testimony as to the wetting episodes and their pattern of occurrence. In the majority of cases, there is no difficulty deciding that the wetting is a case of enuresis.

There are two general categories of enuretics. The primary, also called persistent, enuretic and the secondary, also called transient or neurotic, enuretic. Four fifths of the cases are primary, which means that a period of sustained dryness has never developed and the patient has never known the confident feeling of retiring without worry of enuresis. The secondary enuresis appears after a person has stopped wetting. A neurotic conflict, such as the birth of a sibling, or a transient emotional stress, such as making an adjustment to military service, may precipitate enuresis. Here the enuresis is a regressive phenomenon.

The physician must note whether the enuretic episodes are diurnal, nocturnal, or both diurnal and nocturnal. Although nocturnal enuresis is by far more frequent, a history of occasional diurnal lapses occurs in about 40 per cent of child enuretics. It has been

estimated that at least 1 out of every 1,000 enuretics has an associated encopresis (involuntary passage of feces).

Differential Diagnosis

Usually, the pattern of enuresis is clear cut, and the doctor has no trouble deciding that there is no demonstrable pathology. For instance, the patient remains in good health, he may wet selectively (e.g., at home but not on trips), there are no laboratory or physical findings, and there may be a family history or past history of enuresis.

Epilepsy can usually be distinguished from enuresis by the presence of other stigmata of paroxysmal cerebral dysrhythmia, such as auras, tongue biting, convulsions, and postictal states. Less frequently, one must differentiate sleep-walking, with concomitant urination, and enuresis. However, since enuretics are more likely to be sleep-walkers, the differentiation, if it exists, may be of only academic importance.

Treatment

The time-honored counsel to parents that the enuresis will cease when the child grows up seems, with certain exceptions, to be true. Although most children are dry by age 10, any child who is enuretic should be treated early, since at present it is impossible to distinguish the child who will continue to suffer enuresis into adolescence and adulthood.

General treatment. Although the treatment of enuresis depends on the individual factors in each case, some general measures should be observed in all cases.

First, the patient must have a thorough physical examination, a urinalysis, and a family history study. In cases of both diurnal and nocturnal wetting where there is urgency and frequency, the doctor may wish to observe the patient pass his urine. Some cases may require additional procedures, such as x-ray or brain wave studies.

Second, the therapist must do all he can to promote trust, confidence, and respect. The patient must wish to correct his problem. Often the therapist, by indicating his confidence that the patient can accomplish such a correction, overcomes the largest barrier to successful treatment. The rapport between therapist and patient doubtlessly accounts for the marvelous success that all sorts of therapies have had on enuresis throughout history. Yet, since success is inconstant, unpredictable, and uneven, better treatment methods are necessary.

Third, in the case of child patients, the therapist must reassure the parents concerning the frequency and possible course of the disorder. The doctor must help the parents, particularly the mother, to truly want the child to be rid of the complaint. Usually, it will be necessary to have some sessions with the mother to allow her to ventilate her feelings and to receive psychotherapeutic support. The parents must learn to deal consistently with the patient and to

convey to him, in a gentle but definite manner, that they wish him to stop bed wetting.

Specific treatment methods. The therapist may elect to use one or more specific treatment methods, including psychotherapy, drugs, conditioning devices, bladder-training exercises, hypnosis, and sleep interruption. If there is no response to the treatment within 3 months, the therapist must consider a reevaluation of the case. Although in nearly one half of such reevaluations an organic lesion is found, the lesion may not be the entire cause of the enuresis.

Psychotherapy. When psychotherapy is the selected treatment, individual therapy for the patient is enhanced when the mother or spouse is also in individual or group psychotherapy. Especially in pediatric situations, the results depend a great deal on the response of the mother to the treatment process—both hers, if she is in treatment, and the child's. Psychotherapy is an especially effective treatment with young adult females.

Drugs. A great variety of drugs has been used in the treatment of enuresis. The current armamentarium includes the following: (1) anticholinergics, such as tincture of belladonna and atropine sulphate, which inhibit the detrusor muscle during the night and may lead secondarily to an enlarged bladder capacity; (2) central nervous system stimulants, such as amphetamine and caffeine, which promote a lighter sleep, enabling the patient to awaken to void; (3) antidiuretics, such as posterior pituitary snuff, which reduce urinary output and thus aid nocturnal polyuria or diminished bladder capacity; (4) psychotropic drugs, such as chlorpromazine and meprobamate, which lessen anxiety and help break the cycle of worry over failure to be dry, and increasing enuresis; (5) hormones, such as chorionic gonadotropin and methyltestosterone, which increase genitourinary tract maturation; (6) antihistamines, such as benadryl, which are used where enuresis may be due to a specific allergy that produces a hyperirritable bladder mucosa with resultant urgency and involuntary urine passage; and (7) imipramine hydrochloride (Tofranil). As with all drugs, conflicting results with Tofranil have been reported. The mechanism of action is not clear and may involve the drug's effect on delaying micturition.

Conditioning device. In most cases the most effective way to banish the symptom of bed wetting is to employ a conditioning device that awakens the subject by an alarm bell or a buzzer as soon as a drop of urine contacts a wire pad on which the subject sleeps. The conditioning process quickly leads to cessation of bed wetting, since the patient learns to awaken and void before the stimulus of the bell or buzzer. Although relapse may occur, it is handled easily in most cases by another brief retreatment with the conditioning device. Although no substitute symptoms develop following conditioning, adjunctive psycho-

therapy is often helpful to correct serious family psychopathology when conditioning devices are used.

Bladder training. In cases of primary enuresis, bladder training exercises designed to increase the vesical capacity are successful. The patient may force fluids, wait as long as possible before voiding, and record the volume of urine excreted. Drugs such as oxyphenecyclimine, an anticholinergic, may supplement the voiding charts and bladder training.

Hypnosis and sleep interruption. Hypnosis is effective as a treatment for enuresis and can even be used in children. Sleep interruption by a parent or an alarm clock is useful if the individual is fully awake when he voids. This interruption does not interfere with the patient's health, since the enuretic usually has no difficulty returning to sleep after being aroused.

Suggested Cross References

For information about fundamental concepts of sleep and of conditioning see Sections 2.4 and 3.3, respectively, in Area B, on the basic behavioral sciences.

40.6 NAIL BITING AND THUMB SUCKING

CHESTER M. PIERCE, M.D.

Thumb Sucking

Thumb sucking, like nail biting, is commonplace in our society. It is classified under special symptom reactions as a habit disturbance and is a common habitual body manipulation.

Epidemiology. Thumb sucking is physiological during the first months of life. At about age 1 year the habit ceases. During moments of stress or at nap time and during sleep, thumb sucking may be considered normal until the child is 3. When the activity continues into early childhood, it is considered an indication of emotional turmoil. A fifth of all children past age 6 continue to suck their thumbs.

Etiology. Sucking is a basic physiological need

that has survival value for the human being. In addition, sucking activity is important in the development of the face and jaws and the development of speech.

Thumb sucking may be resorted to as a means of tension release when a person feels tired or insecure. The sucking relieves anxiety by providing an autoerotic oral gratification. Thus, one gains comfort and solace without the presence of another person, such as the mother.

Pathology. There is considerable controversy as to whether or not problem sucking leads to dental pathology. Most authorities believe that, if a person has a good bite and has been provided good dental structures through heredity, the chances of developing malocclusion from thumb sucking are slight. Further, if the deciduous teeth do not become displaced, spontaneous correction of the bite takes place after cessation of the habit.

Management. If an individual sucks his fingers beyond infancy to such an extent that it becomes a problem to his environment and to himself, treatment is indicated. Such problem suckers should have the benefit of dental consultation. Often, for instance, a dental device can aid in reducing sucking through the night.

The parents should be reassured as to the relatively benign nature of the disturbance. It is helpful to secure the child's interest in the success of the treatment to eliminate the symptom. However, the major therapeutic effort must be directed to the general emotional problems that the patient demonstrates. The specific thumb sucking difficulty can be minimized if not ignored.

Nail Biting

Epidemiology. Nail biting or onychophagia is also a means of discharging inner emotional tension. Many adults give a past or present history of nail biting.

Studies indicate that two fifths of all children between the ages of 5 and 18 are nail biters. Girls bite their nails somewhat less frequently than boys. At age 18, the number of nail biters diminishes to about one third of the population studied. Roughly, a fifth of college students are still nail biters. In one study about 10 per cent of graduate students continued the habit.

Etiology. According to the psychoanalytic school of thought, nail biting is generated by intense hostile or competitive impulses toward a parent. Yet, if such impulses were actualized, the nail biter would destroy his dependency gratification source. To resolve this conflict, the patient bites his nails thus denying his hostility, injuring himself, and demonstrating his punishment. At the same time he is able to express aggression but spare the object of his aggression. Nail biting is an oral, sadistic, tension-reducing impulse that is most likely to occur when the patient is bored or anxious.

Management. With young children who do not bite their nails too severely, techniques relying on suggestibility or self-reliance have been successful in eliminating nail biting. The child recognizes that the family is interested in him and that they have confidence that he can master a large problem. Thus, the child may participate in the treatment by means of placebo tasks, such as taking the responsibility to soak his nails daily in olive oil.

In the case of adults or children who have more obvious emotional illness, placebo tasks or studied but supportive indifference to the problem will not be sufficient. In these cases the therapist must attend to the more urgent and more pressing life stresses that result in nail biting.

40.7 CONDUCT DISORDERS AND NEUROTIC TRAIT REACTIONS

ALFRED M. FREEDMAN, M.D.

HAROLD I. KAPLAN, M.D.

Conduct Disorders

Definition. Traditionally, the term "conduct disorder" has been used to refer to manifest behavior disturbances in childhood which are a persistent source of difficulty in the home and/or the school and community. As such, this diagnostic entity is considered to include the entire gamut of behavioral disorders, ranging from extreme provocativeness, dis-

obedience, negativeness, temper tantrums, and cruelty, to asocial behavior, such as precocious sex activity, stealing, truancy, lying, and cheating. The atypical child usually manifests a constellation of such disorders. However, they may also appear as transient phenomena in the course of normal development. Conduct disorders may be adaptational or reactive; they may be neurotic or psychotic; or they may be organic in origin.

Etiology. These disturbances have been attributed to a wide range of etiological factors. For the most part, conduct disorders are considered to represent a failure on the part of the parents with respect to the socialization of the child, which, in turn, has given rise to poor impulse control. However, conduct disorders may also represent neurotic formations, such as counter-phobic aggression or compensation for ego weakness. Thus, many varied and complex hypotheses may be advanced to explain the psychodynamics of a single disorder. For example, a temper tantrum may represent an overt expression of aggression, due to poor ego or superego control; rebellion against authority; an attempt to control the mother; compensation for low self-esteem; or a desire for punishment, due to poorly warded off guilt feelings. Any one of these explanations may be appropriate in a specific case; but it would be fallacious to ascribe all temper tantrums arbitrarily to the same etiological factor.

Accordingly, within this volume, discussion of the etiology and treatment of conduct disorders in childhood will necessarily vary, depending on whether such disorders are classified as "healthy responses," i.e., transient reactive disturbances; as special symptom reactions; or as indicative of underlying personality disorder or brain damage. Clearly, this diagnostic category, per se, is too broad to be meaningful, except for descriptive purposes.

Neurotic Trait Reactions

Definition. The category of neurotic trait reactions is equally ill defined, in that it encompasses such diverse phenomena as somnambulism, tics, stammering, habit disturbances, hyperactivity, and phobias. On another level, neurotic traits are described as pre-neurotic symptom reactions (which may, or may not, signal the onset of an organized neurosis or psychosis).

Etiology. Like conduct disorders, each of the specific neurotic trait reactions listed above may be attributed to one of several etiological factors. For example, in this volume, phobias in childhood are discussed in relation to psychoneurotic disorders, on the one hand, and the significance of school phobias as transient atypical phenomena is explored in another section.

Diagnostic Classification

Both conduct disorders and neurotic trait reactions are included in the American Psychiatric Association's

standard nomenclature under "Adjustment reactions of childhood." However, as indicated above, this category has long been recognized as unsatisfactory. In their report on the proposed reclassification of psychopathological diseases of childhood, the Committee on Child Psychiatry of the Group for the Advancement of Psychiatry (GAP) has wisely eliminated "conduct disorders" and "neurotic trait reactions" from their diagnostic schema and substituted the nosological designation of "tension-discharge disorder" instead. Relevant passages from the detailed discussion in the GAP report of the considerations which precipitated this decision, together with a description of the new clinical entity, are quoted below:

Children in this category exhibit chronic behavioral patterns of emotional expression of aggressive and sexual impulses which conflict with society's norms. They act out directly their feelings or impulses toward persons or society in antisocial or destructive fashion, rather than inhibiting or repressing them and developing other modes of psychological defense or symptomatology. The terms, *antisocial personality*, *psychopathic personality*, *impulsive character*, and *sociopathic personality*, as well as *dysocial personality*, *affectionless character*, *acting-out personality*, *neurotic character disorder*, *primary behavior disorder*, *neurotic behavior disorder*, and *conduct disorder*, have been used by different workers to designate differing individuals in this category, suggesting several subcategories.

In considering carefully this broad category, the Committee drew upon the basic conceptual framework set forth earlier. The terms, *psychopathic*, *sociopathic*, and *antisocial*, were felt to imply too fixed a pattern to apply to many children, even though such personality disorders may become chronic and difficult to treat by the late school age or early adolescent period. "Acting-out" seemed too broad a term; this pattern may occur in a variety of personality pictures or in different developmental phases, and the term is used differently by professional persons from differing conceptual backgrounds. To some, the term *character disorder* is inextricably entwined with moral judgments, which may not be appropriate clinically. *Conduct disorder* and *behavior disorder* seemed such broad terms as to have little meaning. *Primary behavior disorder* implied a type of distinction between primary and secondary etiological factors that may be difficult to support in individual clinical situations.

Aggressive, destructive, or antisocial behavior may of course be seen in many children exhibiting reactive disorders, developmental deviations, or developmental crises in adolescence. Such behavior may occur as part of a picture involving brain damage, mental retardation, or a psychosis. Furthermore, some children in economically deprived urban areas may show behavior which is in conformity with the group code or mores of the neighborhood or gang but which is regarded as antisocial by society at large. Such children may function adequately in certain ways, however, and may show evidence of some conscience formation in their loyalty and codes of honor within their own groups. Many of them in later life can adjust their moral code, within limits, to that of society, although the possibility of continuing antisocial behavior is of course greater than in other categories.

Despite its dissatisfaction with many of the terms discussed in the foregoing, as they apply to children, the Committee felt that certain concepts were valuable and pertinent. The term *impulsive character* touches upon the central problem of difficulty in establishing impulse controls characteristic of certain of these children. The concept of *neurotic personality*, implying the existence of neurotic conflict underlying the behavior of other children, also seems clinically relevant, despite some terminological limitations. *Dysocial* or *asocial*, while constructively implying the discrepancy be-

tween the child's local environment, where his behavior is appropriate, and that of society at large, seems to imply also some lack of capacity for socialization which may not at all be the case in terms of the child's relationships within his own subcultural group. Furthermore, the term *dysocial* leaves little room for the child whose personality functioning is different from the majority because of his particular ethnic, racial, or other subcultural background—as in the child of a family from a society which utilizes magical concepts in its everyday thinking.

Tension discharge disorder. For these and other reasons, the Committee determined to employ the term *tension-discharge disorder* for the major category, with two subcategories subsuming the impulsive or impulse-ridden group and the group of children in whom neurotic conflicts seem to play so large a role. Tension-discharge disorder, while having limitations (as with any term), seemed to the Committee to convey best its conceptual recognition of the central tendency of these two groups, albeit from different sources, to discharge, rather than to delay or to inhibit, impulses unacceptable to the larger society. The group exhibiting deviant behavior on a subcultural basis was put into a separate major category of personality disorder (sociosyntonic); this was done to permit classification of children with various kinds of deviant personality patterns, over and beyond aggressive ones, and to emphasize the "fit" between the individual personality and the subcultural group, rather than the lack of capacity for socialization.

1) *Impulse-ridden personality*: These children show shallow relationships with adults or other children, having very low frustration tolerance. They exhibit great difficulty in control of their impulses, both aggressive and sexual, which are discharged immediately and impulsively, without delay or inhibition and often without any regard for the consequences. Little anxiety, internalized conflict, or guilt is experienced by most of these children, as the conflict remains largely external, between society and their impulses. (Some internalized conflict may be present, and some overlap exists among children with neurotic personality disorders.) The basic defect in impulse controls appears to be reinforced by a deficit in conscience or superego formation, with failure to develop the capacity for tension storage and for the postponement of gratifications. Such children ordinarily exhibit primitive defense mechanisms, with strong denial of dependent or other needs, projection of their hostile feelings onto adults or society, and rationalization of their own behavior.

Children in this category often have a history of extreme emotional deprivation during infancy and early childhood, marked by frequent and prolonged separations from mothering figures. A large number of them come from lower socioeconomic or social class groups, although they may be found at any level of society. Some constitutional tendencies toward motoric discharge of tension rather than other avenues of handling tensions may be noted. A number of these children show abnormally dysrhythmic electroencephalographic tracings, usually without evidence of true epileptic patterns, and a certain group may show a high association between enuresis since infancy and fire setting. Stealing, fire setting, vandalism, destruction, aggressive attack, and other antisocial acts may frequently occur, and behavior may shift at times from one to another or several others; addiction is not infrequent in older children and adolescents. Although their judgment and time concepts are poor, they usually have adequate intelligence and their reality testing in certain areas is quite effective.

Children who have chronic brain damage without emotional deprivation may show a somewhat similar picture, so far as difficulties in impulse controls and judgment are concerned. They usually have adequate capacities for relationships, however, and may show marked guilt, with evidence of true conscience formation.

In recording this diagnosis, the specific behavioral manifestations should be drawn from the Symptom List.

2) *Neurotic personality disorder*: These children may show

behavior superficially similar to that of the impulse-ridden personality as they act out or discharge tension arising from conflict. They appear, however, to have reached a higher level of personality development, revealing strong influence from earlier repressed neurotic conflicts. Their behavior often assumes a repetitive character, with unconscious symbolic significance to their acts, rather than the predominance of discharge phenomena. Evidence of some conscience formation is manifest from the presence of conflict, accompanied by some apparent anxiety and guilt, the latter leading them at times unconsciously to invite limits or punishment. Impulse controls appear to operate to some extent in the absence of exacerbations of conflict. Their antisocial action, when it occurs, is predominantly a reaction to intensification of conflict rather than the sudden discharge of impulses, as in the impulse-ridden type, or the result of limitations in ego controls, which at times are noted in certain brain-damaged children. Relationships are warmer and more meaningful, although often highly ambivalent. Some overlap with the impulse-ridden disorders of course exists. Many of these children during middle or late adolescence have been referred to as neurotic characters or neurotic criminals. As with the impulse-ridden group, the specific behavioral manifestations should be listed with the use of the Symptom List.

Finally, one consideration, implied in the GAP report and throughout this section, must be emphasized. The fact that the same symptoms may belong to different categories of disturbances in childhood is not of central concern in this context. Rather, the purpose of this discussion is to underscore the importance of

diagnostic accuracy, which depends on the careful evaluation and differential classification of behavior disorders which, at first glance, may appear to be similar.

Suggested Cross References

The manifestations of conduct disorders and neurotic trait reactions that have been described in this section may also occur in other categories of childhood psychiatric disorders which are described more fully in Chapters 40, 41, and 42 in this area.

Chapter 41

Psychiatric Disorders of Childhood. II: Psychoneurotic, Psychophysiological, and Personality Disorders

41.1 PSYCHONEUROTIC DISORDERS

E. JAMES ANTHONY, M.D.

It seemed paradoxical to Malamud, considering the widespread incidence of psychoneurosis in the population and the glib use of the word "neurotic" not only in academic vocabulary but in everyday conversation, that there was "a surprising lack of unanimity and clarity" as to what was meant by the concept of psychoneurosis.

This "lack of unanimity and clarity" is even more striking with regard to children, so that prevalence figures are well nigh impossible to obtain. Specific reasons for this have been ascribed to the antidiagnostic attitude of the child guidance movement as a whole, to resistance against using nosological entities derived from adult classifications (rather in the way of "hand-me-downs") and to a repugnance to the categorizing of a child "permanently" during years of development and change. In addition, in many clinics there appeared to be an implicit concept of children as more reactive than introversive, leading to a prepossession in favor of such nondescript categories as "behavior," "conduct," "habit," and "situation." In the few surveys which have been carried out, psychoneurotic reactions have shown a frequency ranging between 5 and 20 per cent of all cases, the figure reflecting the orientation of particular clinics rather than an actual indication of incidence. It seems possible that a potent reason for the relative neglect in the use of this particular category of disorder might be attributable to the absence of a systematic delineation in terms pertaining to childhood.

The failure to recognize psychoneurosis in preadult life is also part of the age-old scotoma for serious emotional disturbances in children. For example, in

1798, in his classification of mental disorders, the philosopher Kant found it possible to state categorically that there was no such thing as a disturbed child. The view was generally accepted for the next hundred years against all evidence of experience, and it was not until Freud that the question was reopened.

In a brilliant series of logically linked clinical and theoretical inquiries, Freud gradually demonstrated the scientific validity of the poetic truth that the child was father to the man, and the neurotic child father to the neurotic man. In the first instance he found that adult neurotic patients almost invariably gave a history of having undergone a similar type of disturbance at some time during their childhood. At this period, the behavior was more likely to be referred to as "naughtiness" and, as he put it, to be "shouted down in the nursery." As he came to scrutinize the childhood situation retrospectively and then directly, he began to recognize the disturbance for what it was, an authentic psychoneurotic reaction. As a result of still further investigation, this clinical neurosis of childhood was seen to be an exaggeration of an underlying developmental conflict that was less discernible. Freud called this disturbance the Oedipus complex and looked upon it as crucial in the development of both childhood and adult neurosis.

This concept of "infantile neurosis" has since occupied a central position in the psychoanalytic theory of neurosis, but, as Hartmann has pointed out, it is not so easy to specify its actual nature. It was Hartmann's view that the pendulum has swung in the opposite direction from there being no recognizable neurosis of childhood to the point when "every naughtiness, actually every behavior of the child that does not conform to the textbook model, every development step that is not according to plan, is considered as neurotic," as a result of which "the broad range of normal variations of behavior is not recognized, and the specific features of . . . a neurosis get lost." He was also of the

opinion that many of the very early neuroses were really different from what occurred in the adult and were usually limited to a single functional disturbance. "The way from conflict to symptom seems often to be shorter than in adult neurosis."

Etiology of Psychoneurotic Reactions

The normal developmental conflict is at first largely external, stemming from incompatibilities between the child's needs and the external demands of the environment. Gradually, the external demand is internalized, and the developmental conflict disappears, since the balance has shifted from the need to gratify pleasurable impulses to the need to comply with the new internal representatives of the external order. With each resolution of conflict in the child, there is a further step towards the formation of the normal adult personality, but when the conflict is unresolved two forms of neurotic disturbance tend to occur. The first is circumscribed and restricted to the phase of the conflict, i.e., the premorbid history seems relatively peaceful, the parents are more helpful than harmful, constitutional factors are slight, and the prognosis fairly good. The second and more common form is a diffuse neurotic disturbance which presents itself as a polymorphous mixture of two or more neuroses. The clinical picture lacks definition, and the pathological processes seem potentially capable of developing in several different directions which are difficult to predict. There is often gross familial pathology with a plethora of constitutional dispositions. In contrast to the first form, the defense mecha-

nisms employed tend to be more various and primitive. As a result of the multiple fixation points, a sequence of different psychoneurotic reactions appears during the course of development.

Clinical Features of Four Types of Childhood Neuroses

In his classical studies, Freud described four different types of childhood neurosis, three of which had later neurotic developments in adult life. This well known series of cases is shown in tabulated form in Table I, exemplifying some of Freud's important conclusions that: (1) psychoneurotic reactions in the adult are associated frequently with psychoneurotic reactions in his childhood; (2) the connection is sometimes continuous, but more often separated by a latent period of non-neurosis; (3) infantile sexuality (both fantasied and real) occupies a memorable place in the early history of the patient.

There are certain differences worth noting in the four cases shown in Table I. First, the phobic reactions tend to start at about 4 or 5, the obsessional reactions between 6 and 7, and the conversion reactions at 8. The amount of background disturbance is greatest in the conversion reaction and the mixed neurosis, and it seems only slight in the phobic and obsessional reactions. The course of the phobic reaction seems little influenced by severe traumatic factors, whereas traumatic factors (e.g., sexual seductions) play an important role in the three other subgroups. (It was during this period that Freud had elaborated his "seduction hypothesis" for the etiology of the neu-

TABLE I
Classical Psychoneurotic Reactions of Childhood^a

	Conversion Reaction (Dora)	Phobic Reaction (Hans)	Obsessive-Compulsive Reaction (Rat Man)	Mixed Psychoneurotic Reaction (Wolf Man)
Family history	Striking family history of psychiatric and physical illness	Both parents treated for "neurotic conflict" but not severe	No family history of mental illness	Striking family history of psychiatric and physical illness
Symptoms	Enuresis and masturbation 6-8 yrs. Onset of neurosis at 8. Migraine, nervous cough, and hoarseness at 12. Aphonia at 16. "Appendicitis" at 16. Convulsions at 16. Facial neuralgia at 19. Change of personality at 8 from "wild creature" to quiet child	Compulsive questions at 3-3½ yrs., regard to sex difference. Jealous reaction to sibling birth at 3½. Overt castration threat. Overt masturbation at 3½. Overeating and constipation at 4-5. Phobic reaction at 4-5. Attack of flu at 5 worsens phobia. Tonsillectomy at 5 worsens phobia	Naughty period at 3-4 yrs. Marked timidity following beating by father at 4. Recognizing people by their smells as a child ("Renifleur"). Precocious ego development. Onset of obsessive ideas at 6-7	Tractable and quiet up to 3¼ yrs. "Naughty" period at 3¼-4 yrs. Phobias at 4-5 with nightmares. Obsessional reaction at 6-7 (pious ceremonials). Disappearance of neuroses at 8
Causes	Seduction by older man. Father's illness. Father's affair	Seductive care by mother. Sibling birth at 3½	Seduction by governess at 4. Death of sibling at 4. Beating by father at 4	Seduction by older sister at 3¼. Mother's illness. Conflict between maid and governess

roses in terms of which the obsessive-compulsive and hysterical reactions were alleged to originate in active and passive sexual experiences.)

Classifications of Neurotic Reactions

Since these classical descriptions were made, clinicians working directly with children have made many attempts to classify the psychoneurotic reactions of childhood in accordance with their experience, and Table II summarizes the more significant attempts at this. It will be noted that the classification tends to vary with both *time* and *country*. The diagnoses of neurasthenia and psychasthenia have given place to anxiety and obsessive-compulsive reactions. Phobias are the most commonly represented, and hysterias are sometimes excluded. Such labels as "hypochondriasis," "tics," "psychosomatic states," and "depression" are peculiar to certain authors. The inclusion of depressive reactions appears to be gaining ground.

In the report by the Group for the Advancement of Psychiatry (GAP) on the classification of psychopathological disorders in childhood, an attempt has been made to define the psychoneurotic reactions in childhood in terms acceptable to anyone working broadly within the psychoanalytic frame of reference. According to the definition offered by the committee, *psychoneurosis in childhood* is said to occur as a result of unconscious conflicts over the handling of sexual and aggressive impulses which, although repressed, remain active and unresolved. These conflicts derive from the relationship of the child to significant family members and belong almost exclusively to the pre-school years. During early childhood such conflicts may be expressed in various symptomatic reactions, but in older children they become internalized and relatively encapsulated and tend to be chronic. Many of the milder reactions may resolve spontaneously as the child reworks the conflicts at a later stage of development and higher level of maturation. The response to treatment is also generally good. The symptomatology is composed of both positive and negative phenomena, the former comprising such reactions as obsessions, conversions, dissociations, and depressions, and the latter being manifested by the absence of a demonstrable organic pathology, a consistent and lasting deterioration in intellectual function, a primary disturbance of mood, and a persistent distortion of external reality. The differential diagnosis includes reactive disorders, developmental deviations, crises within healthy development, and certain predominantly physical disorders which have a symptomatic resemblance to the psychoneurotic picture. These various conditions may also act as precursors in the development of a full psychoneurosis, depending on an intensification and internalization of the conflict. In certain instances, the precipitating situational stress may be so overwhelming and unexpected to the child as to produce a "traumatic neurosis" which may

TABLE II
Various Classifications of the Psychoneurotic Reactions of Childhood

Year	Author	Classification
1920	Pearson (U. S. A.)	Disturbances of sociopsychological adjustment due to emotional conflicts. 1. Anxiety, acute and chronic. 2. Psychoneurosis: gastrointestinal dysfunction, upper and lower; urinary dysfunction
1932	Henderson and Gillespie (Britain)	Anxiety psychoneurosis, hysterias, phobias, obsessions, compulsions, tics (some)
1933	Krasnogorski (Russia)	Subcortical type: neurasthenia, psychasthenia. Hypodynamic (an- ergic) type: hysteria
1936	Miller (Britain)	Subjective disorders: overt anxiety, phobias, compulsions, nocturnal disturbances
1937	Brown (U. S. A.)	Hysterical, psychasthenia, neurasthenia and anxiety types
1937	English	Acute diurnal and nocturnal anxiety attacks. Chronic anxiety states and phobias
1947	Gerard (U. S. A.)	Nocturnal anxiety, phobias, compulsions, depression, chronic anxiety states
1948	Pacella (U. S. A.)	Acute and chronic anxiety states, phobias, compulsions, conversion phenomena, tics, psychosomatic states

1966	GAP Report	Anxiety, phobic, dissociative, obsessive-compulsive, conversion and depressive types

be either a severe reactive disorder or a sudden crystallization of a latent, or subclinical, psychoneurotic state. In certain cases, for reasons not completely clear, symptom formation may not occur. Instead, the personality structure of the child may be affected by neurotic conflicts, altering the patterns of reaction to internal demands and adaptations to the environment, and these may assume the character of personality traits which cause little or no conscious (ego-syntonic) anxiety. When these seeming "personality traits" become fully crystallized, they coalesce to form a personality disorder.

In the milder cases, the differentiation of abnormal from normal reactions presents some degree of difficulty, since various investigations have shown that almost every child manifests various symptom constellations at different stages of his development, and that these include neurotic traits which, if transient, do not require treatment. For example, sleep disturbances may occur in the 2nd and 3rd year, phobias in the 4th and 5th year, obsessional "games" from the

6th to the 8th year, and a large assortment of anxieties involving disease, disfigurement, disability, and death, from the 9th year onwards.

Role of Anxiety

There have been more recent attempts to base an understanding of psychoneurotic reactions on the modes of adaptation of the individual to such primary disturbing affects as anxiety and depression. Adaptation has been viewed from various theoretical positions in terms of defense, avoidance, and problem-solving techniques. Freud himself came to regard anxiety as playing a primary role in the development of all other types of disordered behavior, the elements of which could be regarded basically as techniques for reducing or avoiding anxiety. In the second of his theories concerning anxiety, it was anxiety which led to repression and not the reverse. Freud also began to see the intimate connection between special forms of defense and particular types of psychoneuroses as, for instance, between repression and hysteria.

The vicissitudes arising from the emergence of anxiety may result in a variety of counteractions on the part of the individual. For example, the anxiety may remain undefended, without an object, and experienced both psychologically and physically, as in the typical anxiety reaction; or it may be displaced onto some symbolic object or situation, as in the phobic reaction. It may be converted into various somatic symptoms as in conversion reactions; or it may overwhelm the individual and cause aimless activity or "freezing" as in dissociative reactions. It may be transposed by means of various repetitions, rituals, and reactions, as in the obsessive-compulsive reactions; or, finally, it may allay itself by self-depreciation, as in the depressive reaction. These techniques are all available to children from a very early phase onwards, and clinically one may see the reaction in relatively pure form or accompanied by one or more of the other neurotic reactions.

Role of Depression

There has been a more recent tendency to treat another basic psychobiological affective reaction, depression, in a similar style. Both anxiety and depression are appropriate reactions under normal conditions of danger and desertion, but both can become abnormal when they occur in inappropriate circumstances, when they persist for an undue length of time, or when the child is unable to make a developmentally appropriate adaptation to them (in this context, Rado interpreted many of the symptoms of neurosis as a misuse of "emergency" mechanisms).

Depression can be viewed as an affect, as can anxiety, and allotted a similar conceptual state. As with anxiety, the individual develops various mechanisms for dealing with depression. Whereas *repression* is one of the psychoneurotic's main modes of defense with

anxiety, in the case of depression with its core feelings of unworthiness and helplessness, *regression* is often the mechanism of choice. The other defenses mobilized against the danger of its emergence include obsessive-compulsive reactions (which magically compensate for loss of self-esteem), reversal of affect (characterized by excitement and clowning), identification with idealized objects, acting out (in the form of delinquency), and the development of psychosomatic states. All these defenses are means of averting the passive experience of helplessness in the face of frustration or disappointment.

Relationship between Anxiety and Depression

The fundamental relationship between depression and anxiety is not perfectly clear. Freud had postulated that, whereas anxiety occurs as a reaction to the prospective danger of losing the object, depression develops with actual or fantasied loss. In the situation of separation, the anxiety reaction is evoked by any threatened removal of the mother, but once she leaves, the child, who cannot as yet distinguish between temporary absence and permanent loss, behaves as if he were never going to see her again, until he eventually learns that her disappearance is inevitably followed by her reappearance. The separation syndrome, therefore, contains elements of both anxiety and depression in varying mixture. At an early stage, loss may be felt in terms of need, and the situation is, therefore, a traumatic rather than a dangerous one. Later on, experience teaches the child that the mother can be present but angry with him, and then loss of love becomes a new, and much more enduring, determinant of anxiety and depression.

Anxiety Reaction

Definition. Anxiety is a form of fear reaction that is different from normal object fear in the following ways: (1) it is diffuse or "free-floating" and not restricted to definite situations or objects; (2) it is not accompanied by any degree of insight into its immediate cause; (3) it tends to be experienced in terms of its physical manifestations, but these are not recognized as such by the individual concerned; (4) it is prompted by anticipation of future threats against which current avoidance responses would not be effective; (5) it is not controlled by any specific psychological defense mechanisms as are the other psychoneurotic reactions.

The term "anxiety" is synonymous with the earlier phrase "anxiety state," and the more recent phrase "stress reaction." The still older term is "neurasthenia" in which the emphasis was on the functional disorders of various organ systems and the hypochondriacal preoccupations associated with them. The chief symptoms were of irritability, fatigue, and exhaustion. Hypochondriasis is now regarded as a symptom which can accompany almost any psychiatric disorder.

Epidemiology. Anxiety and fear, varying in degree and nature, are encountered in all young children. Anxiety neurosis has been referred to, not only as *the* neurosis of childhood, but also the form of neurosis which is most commonly reactivated in adult life.

Most of the fears of small children can be traced directly to fears expressed by their mothers, and it is only the occasional fear that seems derived from personal experience. The same was found to be true of fear reactions under conditions of severe external danger, such as bombing raids in London. In situations where the parents felt safe or were not frightened the children remained equally calm.

With regard to chronic anxiety, apprehensiveness on the part of the mother is often clinically correlated with anxiety in the child, sometimes objectless, sometimes well defended, and sometimes wholly denied. The communication of anxiety within families proceeds on both verbal and nonverbal levels, but there is a tendency for anxiety to obtain overt expression at the upper and more articulate levels of social class, and for the "bound" forms to affect the lower echelons. Certain autonomic and endocrine measures, acceptable as indices of anxiety, have shown significantly higher mean values for "neurotic" as compared with control families. Anxiety-prone individuals ("over-reactors") have been roughly estimated to make up between 5 and 10 per cent of a general population. At the level of the child, this would comprise the small percentage of vulnerable children who respond to the "challenge" of "ordinary" experience (sibling birth, illness, hospitalization) with anxiety and regression rather than with growth and maturation.

Etiology. In ontogenetic studies of anxiety, it has been found that the majority of "anxious" children start as early as the 1st month of life to show behavior patterns which later develop into frank expressions of anxiety. The children show stress sensitivity from the very beginning, over-reacting to both internal and external stimuli. They are easily startled and take poorly to change.

The anxious child in a family is often regarded as *different* from his siblings, and the parents usually insist that this quality has been present since birth. Infantile reactions considered indicative of anxiety (apathy, motor excitement, sleeplessness, refusal to eat, and autonomic disturbances) have been related to gross rejection and neglect on the part of the mother. There is also some suggestion that prenatal maternal anxieties, translated into muscular tensions, involving the birth canal, may increase the frequency of abnormal birth conditions which, in turn, enhance the disposition to anxiety subsequently in the child. The anxiety proneness has been followed into the pre-school and early school years. This "constitutional" factor could play a part in determining the clinical picture in later neurotic conflicts.

In addition to physical birth trauma, the tendency

to surplus anxiety has also been linked to the physiological economy and psychological meaning of the birth process. It has been suggested, for example, that the sensorimotor imbalance involved in parturition may be also implicated in the genesis of the later anxiety, but these views are speculative and controversial. Freud, at his most pragmatic, felt that there were many anxieties "without a prototype in birth" and that, in general, the "birth trauma" assumption was entirely unproved and very improbable, since it was hardly credible that the child had preserved, from the act of birth, any other than tactile and general sensations. He did allow, however, that birth might be responsible for a certain predisposition to anxiety and that this might persist over the period of childhood. The neurotic anxieties originating from this predisposition did not seem to be clearly or closely related to the "developmental" neuroses of later childhood stemming from the lack of resolution of the Oedipus complex.

The "predisposition" is further evident in the amplification of the so-called "universal" anxieties—separation anxiety, stranger anxiety, and nocturnal anxiety—normally associated with the early anaclitic relationships.

At the later stage of development, the clinical reaction becomes more complex, the anxiety being generated from three different sources. First, there is contagious anxiety, which is communicated to the child by any neurotically fearful adult with whom he is in close contact. Second, there is traumatic anxiety, resulting from some unexpected fright which overwhelms the child's defenses. Third, there is conflict anxiety, which arises out of the intrapsychic sphere and is the most important source of neurotic anxiety. The three types of anxiety intertwine with one another in a series of relationships or syndromes. There are still unanswered questions as to why only certain anxieties get communicated to the child, why some traumata prove so upsetting and persistent while others have only a minimal and short-lived effect, and why conflict anxiety is often able to resolve itself with the passage of time without treatment.

The transmission of contagious anxiety is governed by such factors as the age of the child, the degree of dependency and suggestibility, the sex in relation to that of the anxious parent, and the closeness of identification. The onerosness of a trauma depends on its intensity, unexpectedness, and significance relative to current conflicts. For a traumatic disturbance to resolve itself, four conditions must be fulfilled: (1) the "environment" should not over-react; (2) the frightening experience should not dovetail into some basic conflict in progress; (3) the secondary gains in the way of solicitude and concern should not be excessive; and (4) the child should be in a state of relative stability in his development.

The resolution of conflict anxiety depends on a

more complex set of factors, especially on the backlog of disturbance built up during the whole course of psychosexual development. There is some evidence that conflict anxiety, insurmountable at one stage of development, may be more easily relieved by more competent ego functioning at the next stage of maturing.

The average neurotic anxiety in children contains elements from all three sources (contagious anxiety, traumatic anxiety, and conflict anxiety), the external factors often having lasting determining effects on the configuration of the basic neurotic conflicts.

Clinical description. The symptomatology of the anxiety reaction includes both psychological and physiological symptoms. The principal psychological symptom is a diffuse and vague feeling of apprehension as if something terrible was going to happen. The anxiety attacks sometimes begin after some manifest trauma, but this is found to be a relative latecomer in the causal chain of events, serving the purpose of externalizing an accumulation of latent, but already existing, anxieties. The trigger events are various and may include a bout of illness, a surgical operation, an exposure to death, or a failure at school. Having their hair washed is apparently a sufficient stimulus for some sensitive young girls.

In addition to the anxious expectation, the children are generally irritable, worried about their health, and prone to episodes of acute anxiety. During these acute attacks, physical symptoms may come to the fore and dominate the clinical picture. These may include disturbances of the heart's action (palpitation, precordial pain, and cardiac symptoms on effort); disturbances of respiration (nervous dyspnea, pseudoasthma, and hyperventilation); gastrointestinal disturbances (nausea, biliousness, diarrhea, and abdominal pain); and attacks of giddiness, trembling, sweating, and paresthesias. Urinary urgency and frequency are also usually present.

Against this background of hypersensitivity and apprehensiveness, it is possible to differentiate three symptomatic groups.

Nocturnal and diurnal anxiety attacks. These attacks are localized at various points on the sleep-waking cycle and are all characterized by acute terror or panic with cataleptic features, profuse sweating, disorientation, and visual hallucinations. A waking terror may be brought about by visual illusions elaborated in the dark; a half-waking terror is often triggered by hypnagogic or hypnopompic hallucinations occurring during the twilight phase between sleeping and waking; a sleeping terror is brought about during light to moderate sleep, when anxiety dreams have their greatest incidence; a sleep-waking terror (the classical "night terror") occurs when the predisposed individual is roused from very deep sleep into half-wakefulness; and finally, at apparently no specific point in the waking portion of the cycle, a "day terror" can occur. This is typically very similar

to the night terror in its clinical picture and may even alternate with it.

The anxiety attacks in these cases are associated with such factors as interparental aggression, mental illness in the family, sleeping in the parental bedroom, undue parental pressures, traumatic experiences, and phobic, anxious mothers who constantly generate an atmosphere of pervasive anxiety in the household by their hyperalertness to threat from any quarter. These sensitive, suggestible, and imaginative children tend to resonate sympathetically in tune with the mother's anxieties.

Chronic anxiety reaction. In certain immature children, there is a permanent attitude of apprehensiveness and an over-reaction to almost every unexpected environmental stimulus. This combination of a lowered stimulus threshold, a tendency to generalize responses, and a protracted lability of affect, causing the child to reverberate for long periods after a disturbing experience, produces a clinical picture of a timid, undecided, withdrawing child who has "always been afraid of everything" and who, through the course of development, has been overwhelmed in turn by separation anxieties, stranger reactions, animal fears, dread of going to school, and general social anxiety. There are no specific attacks of any kind, nor do they confine themselves to any particular object or situation. Darkness, being alone, people, storms, insects, noises are all included in the apprehensions of the child who is sometimes so afraid that he cannot talk above a whisper (Cimbal referred to this reaction as *lebensfeigheit*, meaning cowardliness with regard to living). Nightmares are frequent, enuresis not uncommon, and anxious preoccupation with bodily functioning almost the rule. The child tends to be "delicate" and finicky about food to the constant concern of his equally nervous mother.

Hypochondriacal reaction. A chronic hypochondriacal attitude in the child is made up of current complaints of vague ill health and anxious anticipation of future illness. A variety of factors in the child, the family, and the caring physician may contribute to the genesis of hypochondriasis. Factors in the child include identification with ill parents and siblings and the adoption of familial somatization techniques for dealing with stress; self-mothering in the absence of parental figures; attention seeking aimed at obtaining a greater acceptance and approval within the family; a "flight into sickness" to avoid threatening situations or pressures; reactivation of the sickness role which once obtained for the child a suspension from regular routine and the loving solicitude of the parents; a compensation for social and educational failure linked to a lowering of self esteem; a need to ward off indefinite formless anxiety by the adoption of a definite form of sickness that might be cured; the effect of naive infantile theories of disease that "logically" systematize bodily discomforts; and

above all the atonement for guilt feelings in relation to hostile and sexual impulses and acts.

The parents of such children, particularly the mothers, may be grossly hypochondriacal themselves and may treat the child as a somatic extension of themselves. Their oversolicitude and protectiveness may thinly veil strong feelings of rejection, but, more frequently, the dislike and hostility is relatively unmasked. From time to time, the overprotective mother may "decompensate," giving the child a glimpse of her real attitudes and feelings, and these exposures may in turn set off a reaction of invalidism. Where there is much family history of disease, the anxious anticipation of the parents may fill the child with foreboding about his "inheritance." There is no doubt that some mothers, not necessarily nurses by profession, are at their best in the sick room and enjoy the acts of ministration. The child's "sickness" then becomes an essential part in the relationship with the mother and he literally becomes her "patient." A sick room atmosphere is created around him almost from birth, and he may never have seen himself as a healthy child. The children vary in their reactions; they look and act worried. Hypochondriasis is very much a family disturbance, and the various members seem to understand unconsciously the child's need to be surrounded by as much somatic anxiety as possible. The family may react, in fact, calmly and unconcernedly in the presence of actual illness.

Differential diagnosis. In the child, an anxiety neurosis sooner or later tends to crystallize into one of the anxiety-bound neurotic reactions. The diffuse reaction needs to be distinguished from the reactive disorders and the psychophysiological disturbances. Although physiological concomitants of anxiety are commonly present in varying degrees, they do not ordinarily lead to structural changes in the organ systems involved. Various habit disorders are often associated with anxiety reactions, and these include sleep disturbances, eating problems, temper tantrums, enuresis, nail biting, masturbation, and stuttering.

Prognosis. The prognosis is related to the stress sensitivity and the predisposition to anxiety accompanying it. Where the development of anxiety has been late, the constitutional factors slight or absent, the birth history uneventful, and the first 2 or 3 years relatively peaceful, the anxiety reaction can be treated as a developmental neurotic conflict with relatively favorable prognosis. On the other hand, where chronic insecurity dates from infancy, and one or both parents are chronically anxious themselves, the possibility of frequent relapses throughout development must be borne in mind, even though the prognosis for the current attack may be good.

Management. A careful physical examination may be reassuring to some anxious and hypochondriacal children, but the dangers of iatrogenesis must be constantly kept in mind, if new complaints and new anxieties are to be avoided. The physical examination is

undertaken to assure the doctor that he is not dealing with organic disease and to assure the child that his body is in fact a well functioning entity that might be best left alone to its own "wisdom." Like many other psychiatric disorders of childhood, the conflicts of the child are often maintained and magnified by the anxious intrusions of the parents. Psychotherapy with the child should, therefore, be coupled with guidance for the parents and, if necessary, psychiatric treatment when anxious concerns have reached neurotic proportions. The parents particularly need help when the repressed hostility of the anxious child comes to the surface with psychotherapy and is carried back into the home. With hypochondriacal children, a necessary maneuver, early in treatment, entails a cutting down on medication. This should be done gradually and carefully, since the child has come to rely on its magical efficacy and the support should not be removed too hastily. When anxiety is acute and disruptive and sleep much disturbed, the tranquilizing group of drugs may tide the child over a rough period before psychotherapy is able or available to control his anxieties.

Phobic Reaction

Definition. In this category, the child displaces the content of his original conflict onto an object or situation in the external environment which has some symbolic significance for him. Among the feared external objects or situations frequently chosen by children are animals, school, dirt, disease, high places, elevators, and dying. This condition was formerly classified as "anxiety hysteria."

Epidemiology. It is difficult to assess the incidence of phobic reactions, because they are so often confused in clinics with the presence of fears. Fears occur regularly during the development of a normal child, and certain types of fears are characteristic of certain stages of development. The infant is frightened by any intense, abrupt stimulus and loss of support; between 5 and 9 months, he shows fear of the unfamiliar in terms of persons, things, and situations; between the ages of 2 and 3 years, animal fears are predominant; fear of the dark does not usually begin until the 3rd year, and, as the child grows older, darkness becomes a contributing factor, if not the main cause, in a great many fears. Since a state of darkness is often equivalent to a state of being alone, regardless of presence or absence of others, darkness makes the child feel more vulnerable and less able to cope and thereby stimulates his basic anxiety with respect to separation from the mother. According to Gesell, between the ages of 3½ and 4½ years, the child wakes in fear from an animal dream, "specially of wolves" (as in the case of the Wolf Man). During the pre-school years, there is a gradual increase in animal fears, first of eating and biting animals, and later of overpowering and destructive animals. Many of the fears of children at this age also pertain to possible

injury through drowning, fire, and traffic accidents. As the child grows older and is increasingly able to take account of the past and anticipate the future, his fears are formulated increasingly in terms of remote or imaginary dangers or in terms of misfortunes that do not immediately threaten him but might befall him at a future time. Finally, during the adolescent period, fears and anxieties relating to physical inadequacies and asymmetries, intellectual inadequacies, and sexual functioning may arise.

The problem of differentiating fears from phobias, or healthy from morbid fears, becomes increasingly difficult as one finds that many of the normal developmental fears of children have never been experienced and are often quite irrational. In addition, the reaction of the child to a simple fear often seems to be disproportionate, persisting for long periods of time. It would, therefore, seem as if many of the simple fears of the preschool child may actually represent phobias in which an apparent "neurotic anxiety" is hidden behind an apparent "object of anxiety" the internal danger being transformed into an external one. If this is true, then phobic reactions are probably much commoner than would be supposed from examination of clinical records. As transient reactions, they may never be referred beyond the pediatrician. In guidance clinics, the phobic reaction is seen most frequently between the ages of 4 and 7 years, and equally in boys and girls.

Etiology. In the normal process of development, children outgrow their susceptibility to the anxiety-producing situations of being alone, of being in the dark, and of encountering strangers. Later the animal phobias also gradually disappear. It is, therefore, the *persistence* of this infantile phobic tendency that characterizes the neurotic in the making.

In the immediate premorbid history of the phobic child, one frequently encounters a period of "objectless anxiety" marked by restlessness, irritability, and "naughtiness." Then comes an incident (for example, the horse falling down in the case of Little Hans), and almost immediately there is a restructuring of internal forces leading to a diminution of general anxiety and to the formation of a phobia. In Freud's account, the boy's anxiety begins as a "free-floating" disturbance. Gradually, this diffuse anxiety focuses around questions involving differences between the sexes. Even after the outbreak of the street phobia, Hans is unable to say what it is that he fears. He only admits that in the street he misses his mother and does not want to be away from her. However, when he goes with her for his next walk, he still suffers from generalized anxiety, making his explanation manifestly inadequate.

The next thing, as Freud put it, is "for his anxiety to find an object," and this happens when he later confides to his mother his fear that a horse would bite him. Still later, in the evening, he expresses his further fear that a horse would come into the room. At

this point, the average parent might have justifiably become impatient with such "foolish fears," but, as Freud remarks, "a neurosis never says foolish things." The clarification of this very meaningful "nonsense" occupies the next few months. It is possible that the choice of phobia has some relation to a frightening, infantile experience, but more often than not, the connection between phobia and the primary fear has been lost. Relations between the inner conflict and the specific content of the phobia is also obscure and complex but may be discovered after prolonged clinical study.

In a quite different frame of reference, that of avoidance learning theory, a noxious object or event may acquire aversive properties (fear arousal), and responses which appear in an attempt to avoid the stimuli are reinforced by fear reduction. The anxiety-provoking stimuli associated with the particular stimulus can become generalized to other stimuli in the patient's everyday life and result in a general emotional instability.

Clinical description. The clinical picture presented by the phobic child is markedly different from that of the fearful child (see previous section). Constitutional and hereditary factors are generally insignificant. The children are described as physically well, cheerful, amiable, active-minded, with a suggestion of emotional and social precocity.

Three phobic states which frequently present themselves to the clinician as demarcated entities are the following.

Animal phobia. This has been described in various parts of this chapter in relation to Hans and the Wolf Man. As previously pointed out, animal fears and anxiety dreams about animals are frequent between the ages of 3 and 5, and it may also be true that frightening experiences with animal pets are not unusual in this age group. It would, therefore, seem "natural" that in the search for an external object upon which to displace internal danger, the animal would be a first choice.

In his discussion of animism and totemism, Freud observed that a sense of kinship existed between children and animals, as if they were not too far apart in their thinking and feeling, except for the fact, as noted by the child, that animals seemed much freer in their sexual and aggressive behavior and much less hampered by social restrictions. Animals could therefore serve admirably for the projection of unacceptable feelings. Occasionally, the animal phobia may give place to a different type of phobia and, in some cases (the Wolf Man), may be replaced by obsessive-compulsive reactions.

School phobia. Many of the circumstances affecting a child's self-esteem arise in connection with his life at school. Here the child is exposed to failure or threat of failure in both the academic and social spheres. With its traditional focus on competition, the school becomes the situation in which children try

themselves out in many different ways, realizing both their strengths and their weaknesses. The "organism" of the school, as with animals, offers an appropriate and convenient symbol for displacement.

The school phobia proper represents only one type of response within the general category of the child's refusal to attend school. At one extreme, there is truancy, which can be regarded as more a psychosocial than a neurotic problem. The school phobia proper is now regarded as a variant of the separation problem based on neurotic conflicts originating within the home, but sometimes precipitated by something happening in the school, which then serves as a "transference" situation. It has been said that "all of a child's worries, fears, anxieties, self-consciousness, feelings of inadequacy, his relation to his parents, to his siblings, to himself tend to gain reflection in the school situation" (this would also be an apt statement of the therapeutic situation, and it is not unusual for "treatment phobias" to develop, leading to "drop outs"). The crucial psychopathology in these cases has been attributed to an anxiety over separation from the mother and to a concomitant anxiety on the part of the mother with regard to separation from her child, with the establishment of a "symbiotic" relationship in which the two partners are dependent on, demanding of, and dominating each other in turn. At first sight, this would appear to be a "pregenital syndrome" in psychoanalytic terms, but a more careful analysis of some of the cases leads to the suspicion that behind the anxiety of separation from the mother lies, in Freud's terms, "the next transformation of anxiety," castration anxiety, which involves a danger of separation from the genital that is "tantamount to a second separation from the mother" because possession of the genital organ contains a guarantee of reunion with the mother, and the loss of the organ would mean a loss of this guarantee. In this context, it will be recalled that the first explanation put forward by Hans for his street phobia was a fear of separation from his mother, and it was only subsequently in the course of his treatment that the underlying castration anxiety was revealed.

From an examination of a large number of such cases, it becomes apparent that these cases do represent a heterogeneous group, and that the school phobias which begin early are different clinical entities from those beginning, for instance, at puberty or in early adolescence. The latter group tends to comprise severe character disorders and borderline psychoses, and there is often an associated family pathology of some severity, particularly depression in the mother. There is some suggestion, too, that the more "external" types of precipitating factors, involving disapproving teachers, poor grades, bullying, or shameful incidents in which the child "loses face," may all carry a more favorable prognosis than those which are connected with home and fam-

ily, such as illness in the child, illness or death in the family, an accident involving the parents, or the development of mental illness in some crucial figure such as the mother. Often, as if to supplement the phobia, the child may show psychophysiological reactions as well, such as abdominal pain, diarrhea, vomiting, and headache.

Death phobia. This might be referred to as "8-year anxiety," since it tends to occur very regularly at about that age. In his earlier work, Freud referred to the "eight-year boundary line" that seemed to separate childhood. For a while, he believed that anyone who had not been subjected to seductive sexual experiences before 8 years could not develop hysteria. In his case of Dora, neurosis began in her 8th year, and, in the case of the Wolf Man, his "infantile neurosis" ended abruptly around the 8th year. In the earlier studies of Piaget, the 8th year also formed a boundary line between the egocentric child with his magical, animistic, "realistic" tendencies associated with a precausal, prelogical mode of thinking and the "operational" child who sees the world logically and rationally. In many children, at about this time, there occurs what can be described loosely as an "existential crisis." The child becomes preoccupied with ideas of death and dying either about himself or about his parents. Once again, separation anxiety is brought to the forefront; the main presenting fear is that the mother will die; but, again, there is more to the phobia than just this. The child's concept of death, like many of his other concepts, develops gradually during the whole period of childhood. At an early stage, death is thought of mostly in animistic terms in which the dead see, hear, and feel. Later it is viewed as separation, or rather desertion, and, still later, death becomes personified as a dreaded figure removing the loved person. Before the age of 7 death is reversible. At about 8 years, death, for many children, becomes irreversible, and, therefore, death wishes, both conscious and unconscious, take on a new emotional coloring. At the time of the crisis, the child becomes aware of a peculiar kind of helplessness in the face of the inevitability of death, with the additional feeling that no one can help, since everyone else is in the same predicament. An experience of death will sometimes precipitate the crisis or bring it out at an earlier age, but on closer analysis, it soon becomes clear that the emotional conflicts have been growing uninterruptedly since preschool days and that the fear of death is frequently a fear of punishment and retaliation. A coexistence of death wishes with an experience of actual death, coupled with the sudden realization of the irreversibility of the death process thus proceeds to a state of acute panic that leaves the child for a while poorly organized in his defenses and prone to extremely primitive behavior. In fact, at times this panic may take on the appearance of a traumatic neurosis. As the condition improves, the sense of personal immunity to death reasserts itself, and what ex-

istentialists refer to as the nonauthentic position becomes reestablished.

Differential diagnosis. Developmental crises involving separation anxiety with concern for the whereabouts of the mother should be distinguished from phobic disorders with their internalized and structured character. The mild fears and transient phobias of the healthy preschool child and the fears of specific stressful experiences in reactive disorders should also be recognized as distinct from neurotic phobic disorders.

Prognosis. Freud referred to the phobic neurosis of childhood as the model for all repressive disturbances. He was not certain as to the prognosis without treatment. To quote from his *Collected Papers*, Vol. 3, "phobias are well known to be quite extraordinarily frequent, even in children the strictness of whose upbringing has left nothing to be desired. In later life, these children either become neurotic or remain healthy. Their phobias are shouted down in the nursery because they are inaccessible to treatment and are decidedly inconvenient. In the course of months or years, they diminish, and the child seems to recover; but no one can tell what psychological changes are necessitated by such a recovery, or what alterations in character are involved in it." He goes on to point out that in the adult neurotic patient, one frequently finds a residue of the childhood phobic reaction, as if there were a continuous, undisturbed thread of mental activity stretching between the two neurotic disturbances. The symptom is, therefore, transient, but one cannot say the same for the neurotic substratum.

Management. Phobic children are often a pleasure to treat in that, like Hans, they are generally alert, inquisitive, and resourceful in the therapeutic situation and make full use of all the symbolic equations in play, both consciously and unconsciously. In the classical phobic reaction, one is often able to follow the line of displacement back into the central neurotic anxiety that is in part related to troublesome, aggressive wishes, and in part to erotic impulses most often revealed in the dream material and in masturbatory fantasies. For the analytic therapist, Freud's dictum still holds true: "Sexuality is the key to the problem of the psychoneuroses...no one who disdains the key will ever be able to unlock the door."

The child's phobia, especially his school phobia, may create serious problems for the family as a whole. The parents are often understandably concerned as to how far they may proceed with the child in his avoidance behavior, and to what extent they can allow the household to be dominated by the restrictions imposed by the phobia. In most of the phobias, other than the later school phobias, the prognosis for symptomatic cure is reasonably good within a short period of time, and the parents can, therefore, be prevailed upon to resist forceful and punitive measures during the period of therapy. In instances of the

later school phobias, the mother may often be as disturbed as the child, and her disturbance may be aggravated by her knowledge that the child is missing out on schooling. In all cases of school phobia, the parents form an integral part of the treatment program. The current practice is to try to return the child as rapidly as possible to the school environment, since the longer he is away, the more difficult it will be to get him back.

In the case of the death phobia, a tranquilizing agent may relieve the panic that besets the child prior to sleep in the acute stage. This period of time is especially troublesome for children with neurotic problems, since sleep may represent the threat of frightening dreams and possible bed wetting, and being alone in the dark may stimulate conflicts around masturbation. For the child with a fear of dying, falling asleep has special problems in itself, since sleep may both consciously and unconsciously be associated with separation and death. With some acute phobias of recent onset and a clear cut precipitating trauma, Levy's "release" therapy may be highly effective, especially if this is followed up by more traditional psychotherapy. More recently, Wolpe's method of systematic desensitization has been employed in the treatment of child phobic patients with good reported success.

Conversion Reaction

Definition and history. Freud first introduced the concept of "conversion" as a mechanism for transforming anxiety into a dysfunction of bodily structures or organs supplied by the voluntary portion of the central nervous system, involving the striated musculature and the somatosensory apparatus. The symptoms serve to lessen conscious anxiety and to symbolize the underlying mental conflict. Since they also meet the immediate needs of the patients, they serve as a source of "secondary gain." The term "conversion reaction" is synonymous with "conversion hysteria."

Toward the end of the 19th century, the work of Charcot stimulated a great deal of interest in hysteria, and the Nancy School fostered this interest through its work on hypnosis. Freud was in touch with both groups, which prepared him for his subsequent collaboration with Breuer, culminating in the publication of "Studies in Hysteria" in 1893. This contained Breuer's theory of "hypnotic states" and his method of abreaction whereby the original psychic trauma was reproduced in *statu nascendi* under hypnosis. Both theory and method were later disavowed by Freud who preferred the "talking out" of reminiscences. He also rejected Janet's theory that dissociation was the primary mechanism, maintaining that it was effect not cause.

At this stage Freud still believed that the causal trauma was of recent origin, and that once the treatment was applied the hysterical symptoms "disap-

peared forever." He mentioned, for example, the case of a little girl with attacks of general convulsions who had an immediate convulsive attack under hypnosis when she "saw" a dog coming at her. It seemed that her first attack had occurred soon after she was chased by a mad dog. The abreaction was followed by the disappearance of the symptom, confirming its hysterical nature. That dog was a prelude to many theoretical shifts in the years to follow, but at this stage Freud seemed satisfied with its immediate and manifest significance as a causal agent.

In 1894, Freud stated that the crucial mechanisms at work in hysteria included the presence of an unbearable idea, the capacity for conversion, and the readiness to dissociate.

In 1896, he felt that the *character* of the traumatic event helped to shape the quality and intensity of the symptom that followed, but his vision was now focused beyond the traumatic incident and led him to memories that antedated the abreacted trauma and linked it to a series of disturbing events not strung together simply like the pearls on a necklace but much more like a genealogical tree containing ramifications of memory chains branching at nodal points. As he followed the chains, he made two discoveries: (1) that it led him back to the time of puberty; and (2) that the original experience turned out to be a sexual one.

In continuing this investigation, Freud soon found himself looking beyond puberty into the dark period of childhood. Now he was confronted by a dilemma. Since children at this time in history were by definition asexual, it will seem that he must either abandon his sexual hypothesis or his childhood hypothesis. He decided to abandon neither, but rather to incorporate both in a fresh theory that attributed the development of hysteria to the occurrence of actual sexual experiences in childhood below the age of 8 years, which coincided, he noted, with the development of the second dentition. He was now convinced that hysterical symptoms began almost without exception in the 8th year and had to be preceded by a passively endured, unpleasant seduction experience.

He was soon faced with another critical decision when he found that many of the seduction stories told him by patients had never, in fact, taken place, and that he had to either sacrifice his theory of neurosis based on childhood sexual experience or take a closer look at the "lies." It was at this historical point that he reached his "Copernican" conclusion that fantasies were as potent as facts in generating the psychoneurotic reaction and had their own "psychic" reality. In his final etiological step, he brought the infantile sexual fantasies into the overall framework of the Oedipus complex and traced the development of hysteria to the repression of unresolved oedipal wishes. He decided that the wishful fantasies occurred during the early phase of masturbation, and, in conjunction with this, he made the

important clinical observation that the onset of neurosis coincided with the cessation of masturbation, as in the case of Dora.

Childhood hysteria as a clinical condition was first mentioned by Lepois in 1618. From 1873 until 1915, there were 36 publications devoted to the topic; from these it is clear that nearly every conceivable form of disturbed behavior was being included in the concept and that it was used to cover almost any kind of emotional instability. From 1915, the subject almost disappeared from the literature until a special number of *The Nervous Child* was devoted entirely to it. It was apparent that the confusion as to what might be included or excluded from the diagnosis still persisted.

Epidemiology. As Kanner points out, one finds in the literature statements that hysteria is an everyday phenomenon in childhood, as well as contrary assertions that it is most unusual. The gross manifestations of hysteria in the adult have considerably diminished in the Western world, although they can still be seen in primitives and adolescents. About three to five cases of hysterical contractures, aphonias, and amblyopias can be expected in the out-patient department of a children's hospital every year. The milder forms of conversion seen today are usually part of a mixed neurotic disturbance with phobic, obsessional, depressive, and sometimes even psychotic elements. Various authors have also suggested that hysteria is not so phase-specific as was once thought and that it might well have its roots in a primary disturbance at the oral level, which furnished it with a paranoid substructure, and lent "malignant" aspects to the hysterical personality.

At one time, it had been thought that hysteria was restricted to upper class females, but Charcot was able to demonstrate that it also occurred in lower class men, although the rest of Europe felt that this was true only of France, and the rest of France felt that this was true only for Charcot's cases. Conversion reactions still occur predominantly in adolescent girls, but there is no appreciable sex difference during childhood. The incidence below school age is negligible, although cases have been reported as early as 1 to 3 years of age.

In the course of time hysteria has evidently undergone a "downward mobility" through the social classes, since it is now more frequent in working class children and adults. The fact that very few cases of pure conversion hysterias are encountered in guidance clinics has given rise to the erroneous conclusion that the condition is largely nonexistent; but this is far from being the case, since it now appears to occur in milder and more transient forms that are dealt with by the pediatrician. In a study of childhood hysteria in which the diagnosis was made on the basis of multiple symptoms persisting over long periods of time accompanied by the somatic symptoms of anxiety, pseudoneurological symptoms, and/or ab-

dominal pain and vomiting, it was found that hysteria was unusual before the age of 9 and rare before the age of 5, that there was no occurrence of monosymptomatic hysteria, that no males with hysteria were found at follow-up, and that anxiety was a constant manifestation of the condition, suggesting that conversion was not as highly effective in defense as it was classically made out to be. Whether this study by general psychiatrists without training or experience with children actually dealt with childhood hysteria is open to question.

Etiology. In the historical development of psychoanalytic theory, as delineated above, the original neurotic conflict was located successively in adult, adolescent, and infantile periods of life, and the "unbearable idea" was reduced first to a sexual act, and then to a sexual fantasy. At every stage of Freud's theorizing, however, the mechanism of "conversion" was judged to be primary for the hysterics.

For Janet, the primary mechanism was that of dissociation, the dissociated function operating in co-existence with normal consciousness or to the exclusion of other functions. He also called attention to the calm mental attitude, "*la belle indifférence*" which is not so common in childhood but makes its appearance in early adolescence.

So-called naive or common sense psychological theory (as propounded by Heider) might help to explain some of the curious pseudoneurological findings that occur in hysteria. The hysteric behaves symptomatically as if he were totally ignorant of anatomy, and his physical symptoms tend to correspond strikingly to the usual lay concepts of disease. For example, hysterical paralysis shows an exact delimitation and an excessive intensity and is more frequently accompanied by sensory disturbances than organic paralysis. The naive theory of illness would tend to incorporate infantile theories of disease within its framework so that the young child's conception of the body and its relationship to the mind governs the symptomatic picture. In the Ganer syndrome (which may occur occasionally in older children and adolescents) the child's naive concept of insanity is at the basis of the peculiar behavior in which absurd, whimsical, and approximate replies are given to simple factual inquiries. The hysterical attack may be precipitated associatively with the content of the unconscious complex if stirred by a conscious occurrence; organically, if for any reason the emotional investment in a particular part of the body reaches a critical level; in the service of paranoic gain, as a flight into illness when reality becomes too painful or too frightening; and in the service of epinoic gain to achieve some secondary benefit. The choice of the afflicted region is determined by the unconscious sexual fantasies and the corresponding erogeneity of the area, somatic compliance (the point of least resistance), the situation in which the decisive repres-

sion occurred, and the ability of the organ to symbolize the unconscious drive in question.

Clinical description. There are no physical symptoms in the conversion reaction which cannot be produced by volition or by emotion, although it may be possible to maintain these symptoms for only a short time. The motor symptoms include paralyses, tics, and tremors; the sensory symptoms include anesthetics, paresthesias, and hyperesthesias (the distribution is not according to anatomical lines, varies at different examinations, and is susceptible to suggestion); and the visceral symptoms include anorexia, vomiting, bulimia, hiccups, respiratory tics, and various abdominal complaints.

Ocular hysteria occurs in children about as frequently as in adults, with peak frequencies in the 9- to 10-year and the 13- to 14-year groups, and in a sex ratio of 3 girls to 1 boy. In an experimental sampling of patients, vision varied between 20/70 and 20/200, a few individuals having only light perception. None of the children examined experienced any difficulty in getting about, and all showed the constricted tubular peripheral visual fields pathognomonic of hysterical amblyopia.

Hysterical contractures have been reported as "not infrequent" in the 10- to 15-year age group, again with a female predominance ratio of 5 to 1. Precipitating factors include minor trauma or orthopedic procedures. There is usually evidence of secondary trophic changes such as cyanosis and coldness of the part. Psychological factors include disturbed parents and parental relationships, rigid authoritarian attitudes towards the child, and early feeding and behavior difficulties in the child. A period of severe emotional stress coincides with the onset of the symptoms. There are two hysterical syndromes encountered fairly frequently in childhood:

The tic syndrome. Like school phobias, the symptom of tics may be found against several different backgrounds of disturbance. Tics are not uncommon in the postencephalitic syndrome; they may occur with severe character disorders as in the Tourette syndrome, and they may be included in a psychoneurotic reaction. The tic syndrome can be roughly differentiated into two groups. In the first of these, the tic represents a conversion symptom in a "genital" syndrome, and in these cases, tics are usually single and simply patterned. There is often a history of psychological trauma at the onset, and the psychopathology evoked has an oedipal configuration with associated castration anxiety. The family history, apart from mild neurosis, is relatively clear, and there are no conspicuous disturbances in the premorbid history. The child often occupies a special position in the family, such as being the only boy, and his parents, especially his mother, are inclined to pressure and restrict him. From early life, he has shown a tendency to hyperactivity, and the parents have had difficulty

keeping him quiet and still. The EEG is normal. The prognosis with psychotherapy is favorable, and some of the milder varieties may clear up spontaneously within weeks or months.

The second type of tic disturbance has a mixed clinical picture and is generally associated with a neurotic character disorder, sometimes close to a borderline psychotic state. This disturbance has been referred to as a "pregenital conversion reaction," and the psychopathology displays both oral and anal features. Anal sadism, exhibitionism, and voyeurism are prominent, and the symptoms may include coprolalia. Attempts have been made to separate the various parts of the symbolic movement into components representing pantomimes of unconscious, aggressive, and erotic wishes. Whereas the hysterical convulsion appears to be a gross translation of the unconscious wish and fear, the hysterical tic is more in the nature of a compromise movement in which only a fractional part of the impulse gains expression.

Hysterical paresis. This type of conversion response is not uncommon at puberty and is sometimes brought about by a strongly worded suggestion from a parental figure indicating possible loss of function or disability. In the female, there is often a marked ambivalent attitude towards the male, alternatively rejecting and inviting. The girl is usually highly contemptuous and disparaging of boys, refusing to associate with them, and her crude and rough demeanor overlies a masculine identification. She is also outspokenly envious of boys and may list their many unfair advantages. The precipitating factors are often menarche, which serves as a reality conformation of her no longer deniable femininity, and exposure, even indirectly, to some violent sexual incident which may weaken the defense of masculine identification and necessitate the conversion of the emerging anxiety. In the boy, the background is usually one of a passive, feminine character configuration with a submission to parental expectation. The conversion symptom is usually precipitated by a mobilization of anxiety in reference to guilt and punishment associated with pubertal masturbation and an excessively harsh superego structure leading to a marked inhibition of any form of aggression. The biological thrusts of puberty resulting from endocrinological changes often upset the neurotic equilibrium, and previously successful defenses such as masculine identification in the female and feminine identification in the male are no longer adequate.

Differential diagnosis. In adolescents and adults, conversion disorders frequently occur in hysterical personalities, but this is not always the case in childhood. It is also unusual to see a purely hysterical disorder in children, and "combined disorders" are more common, in which a conversion reaction exists along with other neurotic, or sometimes psychotic, disturb-

ances. Conversion disorders must be distinguished principally from symptoms of predominantly physical illness and psychophysiological disorders. Occasionally the psychophysiological disorder and the conversion reaction may be so mixed, as in certain cases of vomiting, encopresis, hyperventilation, and enuresis, that it is difficult to decide to what extent the habit disorder has been drawn into the service of conversion.

Prognosis. The "purer" the conversion reaction and the freer the personality from character disorder, the better is the prognosis. The absence of gross pathology in the parents is also more conducive to a favorable outcome. In a 9-year follow-up of 37 children diagnosed as having hysteria, hypochondriasis, and mixed psychoneurosis, 5 cases presented hysteria at the time of follow-up and 5 anxiety neurosis. The remainder had physical and mental symptoms of various kinds apart from two patients who seemed to be completely well. (However, the terminal comment at the end of the section on epidemiology applies here as well since both refer to the same study.)

Management. Since the time of Charcot, many different treatment procedures have been tried successfully with hysteria, most of them incorporating some mode of suggestion. These have aimed at removing symptoms, but they leave the underlying conflict unresolved. The use of hypnosis with children, especially with girls at puberty or approaching puberty, has iatrogenic dangers attached to it. It is certainly possible to let the child relive hypnotically the episode responsible for the conversion, but it is inevitably treated by some children as a seduction, and they react accordingly. Furthermore, the mere removal of a conversion symptom with all the primary and secondary gains attached to it can bring about resentment at the act of deprivation.

Insight therapy is aimed at uncovering the neurotic conflict that has led to the conversion and at helping the child to "reconvert." In the psychoanalytic mode of treatment, the decoding of the unconscious meaning of the conversion symptom through interpretation induces progressive alterations in the transference relationship and in the symptomatology, until the work of reconstruction pieces together the historical development of the symptom, making use of dreams and fantasies as an adjunct.

As Kanner has pointed out, environmental manipulation is sometimes more successful with hysterical children than with hysterical adults, and he has even suggested the exploitation of such sublimatory activities as dramatics so that the child can learn that "exaggerated acting is bad acting!"

Dissociative Reaction

Definition. Neurotic anxieties belonging to this category may bring about temporary disorganization of the personality which culminates in such aimless

behavior as fugue states, catalepsy, amnesia, twilight states, narcolepsy, and pseudodelirious and stuporous states. Self-representation may be disturbed, with the development of personality dissociation and multiple personality formation. Formerly, this reaction was classified as a type of conversion hysteria.

Epidemiology. This is perhaps the most dramatic of the group of hysterias. At first sight, it appears to involve a process of decompensation and a failure of defense, but on careful inspection it is seen that the fugue states, dream states, somnambulism, and stupor are fairly structured entities which operate behind a curtain of amnesia, so that the conscious ego of the patient is able to state quite blandly that he has no knowledge whatsoever of what he is supposed to have said or done in his other condition. Fugue states have been described in girls around the age of 8 and again at puberty. Somnambulism also is rarely found below the age of 8 and increases in frequency toward the end of childhood. In one series of 193 children, 13 per cent of the cases were diagnosed as having hysteria, 20 per cent showed dissociative reactions, and 80 per cent combined dissociative and conversion reactions. The girls outnumbered the boys about 3 to 1. The incidence appeared higher in children coming from subcultural areas.

Etiology. Janet's theory of hysteria is especially applicable to the dissociative reaction. He regarded the main factor as a disturbance of the synthesis of the personality, characterized by a restriction of consciousness and a tendency to dissociation. Certain functions and ideas are "split off" from the conscious personality, and the more they have been involved in a major affective experience, the more they are apt to become dissociated. Unlike Freud's theory of the repressed conflict, the theory of dissociation does not help to explain why dissociation takes place. It was possible for Janet to cite heavy neuropathic tainting as predisposing to the disturbance, as this was found in many of the cases, especially the more serious. There is sometimes a dissociative tendency in the family, so that the pattern for the symptom can be copied from observations made within the family. The loss of personal identity entailed in this type of reaction is commonly accompanied by amnesia, which is different from organic amnesia in that it occurs suddenly and without trauma and is usually recoverable spontaneously or with the help of therapy. There is no recorded case of a child demonstrating multiple personalities, but fugue states and somnambulism are not uncommon. The predisposition to gross reactions of the dissociative kind includes heavy constitutional factors (although not neurosyphilis in the parents as Freud once thought), disturbed family relationships, and unfavorable environments. Mental or physical illness in the family can act as a powerful model for abnormal behavior in a hypersuggestible, predisposed child.

Clinical description. Children with a tendency to

dissociation seem fairly well adjusted in their normal states though somewhat shy and subdued. More than with the other hysterias of childhood, the dissociative type tends to be monosymptomatic, massive, and acute. Janet has attempted to describe two forms of dissociated state, using somnambulism as a model. In one form, the monoideistic, there is a striking poverty of content, and this is the form characteristically found in children. The "poverty" is in fact relative to the depth and intensity of the treatment process. The deeper the process, the "richer" the clinical content.

Two of the dissociative reactions are among the more frequent in childhood:

Somnambulism. This can be defined as a fugue state which begins during sleep and is usually of shorter duration than a fugue. The movements of the somnambulist seem to be in response to the manifest or latent content of the dream, and the meaning may be an escape from the temptation of the bed or a movement towards a particular goal which represents gratification or reassurance. It becomes increasingly common after the age of 8, reaching a peak frequency around middle adolescence. At the earlier ages, the motivation often appears on the surface such as the acting out of some unconscious wish. In some cases, the approach behavior is prominent, and in others avoidance, but in the majority of cases there may be a combination of approach and avoidance. At the point of greatest ambivalence, the patient may wake up. Compared with children who suffer from night terrors and nightmares, the sleep walker appears to be less intelligent, less imaginative, less prone to conscious anxiety but more suggestible. It has been referred to as a "motor syndrome," sometimes associated with other motor disturbances such as tics. The patient tends to express himself more frequently through activity than in words, and dreaming is somewhat sparse and poorly recalled.

Twilight states. The typical history of a child, typically a female, manifesting twilight states is as follows. The early childhood is usually described as easy and uneventful with a close relationship with both parents. A sibling is born when the child is about 3 or 4 years of age, and soon after, the child, almost predictably, undergoes some traumatic sexual experience with an older person, which the child at first keeps secret but about which there are considerable guilt feelings. At about the 5th or 6th year, there is a realignment in the family. The child begins to show an exaggerated affection toward her mother and alienates herself from her father (in one case the alienation was increased to the point of not recognizing him). The child appears to become increasingly disturbed, and about her 8th year, she begins to suffer from twilight states in which she both reenacts her sexual seduction and at the same time shows marked hostility to the mother. As soon as the attack subsides, she once again reverses her behavior and clings affectionately

to her mother pleading for protection. Afterwards, she shows complete amnesia for the whole event.

Differential diagnosis. Like conversion disorders, the dissociative reaction often occurs in hysterical personalities but may appear in other psychopathological disorders as well. In its gross form, it needs to be differentiated from psychotic disorders, epileptic equivalents, and from analogous symptoms in some other types of neurotic reactions.

Prognosis. The prognosis for any particular dissociative state may be good, since they often disappear spontaneously in the course of a few months, to be replaced by some other symptomatic expression, usually from the same reactive group. One occasionally sees alternations of fugue states, somnambulism, and twilight states. The prognosis is less favorable for reactions beginning in childhood and reactions associated with personality disorders or with dissociative tendencies within the family. The dictum that hysterical parents have hysterical children is probably truer for this group than for any other one of the hysterias.

Management. There is a tendency to treat children belonging to this group like psychotics or borderline psychotics and to hospitalize them for long periods of time. When the reaction takes the form of stupor or catalepsy, the need for hospitalization is understandable. The dramatic and unusual symptoms usually obtain a great deal of professional attention and interest for the child, and one of the epinoic gains is to become an "interesting case." Once again, psychotherapy should be aimed at the underlying conflict situation, rather than the symptom itself. The therapist must strive to remain unimpressed by the symptomatic repertoire of the patient, while giving every consideration to the very real problems engendered by the illness. Hypnosis or Amytal abreaction is often successful in relieving the acute symptoms.

Obsessive-Compulsive Reaction

Definition. In these disorders, the anxiety aroused by the unconscious conflict is counteracted by the occurrence of thoughts (obsessions), acts or impulses to act (compulsions), or mixtures of both which are all isolated from the original, unacceptable impulse. The child often recognizes his ideas or behavior as unreasonable but is, nevertheless, compelled to repeat his rituals. Often the external behavior represents the opposite of the unconscious wish, as with excessive orderliness and washing compulsions overlying impulses to soil and mess. Counting and touching ceremonials or recurrent thoughts appear frequently, resulting in marked anxiety if these are interfered with by the parents or other persons. This category includes many cases formerly classified as "psychasthenia" (Janet) in which phobias, compulsions, and obsessions were accompanied by doubts, timidity, and depressions. Janet considered that a general lowering of "psychological force" was the basic cause of the difficulty, and he felt that the condition had some relation to epi-

lepsy, of which it was perhaps a milder form. Early in his studies, Freud began to notice connections between hysteria and obsessional neurosis. In the first place, he accorded the anancastic reaction full recognition as an illness entity and then drew it into a grouping with hysteria. In the earlier work, he referred to them both as defense neuroses, and later they became the transference neuroses. He regarded the transposition of affects that brought about the clinical picture in obsessional neuroses as equivalent to the conversion of affects that operated in hysteria. He very soon related them both as originating from infantile sex experiences, and in the seduction hypothesis he outlined a schematic relationship in which the premature exposure to sexuality, if passive and unpleasurable, led to the development of hysteria, whereas if active and pleasurable, it gave rise to an obsessional neurosis characterized by self-reproach for the sexual aggressiveness entailed. With his discovery of the Oedipus complex, Freud attributed the development of hysteria to a direct repression of oedipal wishes, and the development of obsessional neurosis to a regression to anal-sadistic levels. Eventually, he delineated the psychopathology of the obsessional neurosis in terms of anal erotism and sadism (which he linked together); bisexuality; defense mechanisms of isolation, undoing, and reaction formation; unusual intellectual drives; and premature ego development.

Epidemiology. About 20 per cent of all cases of obsessional neurosis begin under the age of 15, and 50 to 60 per cent earlier than the age of 20. Of the childhood cases, about half have an acute onset, and the other half develop insidiously. There is a slight preponderance of females, but by no means as marked as in hysteria, and females are more inclined to have an acute onset. About a third of the cases present a mixed clinical picture involving obsessional thoughts, acts, and phobias; about a third are mainly represented by thoughts and acts; a sixth of the cases are predominantly phobic, and another sixth of the cases are also atypical in that the obsessional condition is complicated by the presence of other psychopathological states. The condition, in general, tends to occur in the upper brackets of social class, intelligence, and education. An appreciable number of parents of obsessional children also suffer from obsessional illness (about 10 per cent), and between 40 to 60 per cent show obsessional traits. There is a general consensus that obsessional illness is frequent in the family of obsessionals, and also that more familial pathology is present than is the case in other psychoneuroses (from 4 to 15 per cent of the parents may be psychotic). None of these findings can be offered as proof of heredity, since the effect may well be the result of social conditioning. No twin control studies have as yet been carried out. In a California survey of obsessive-compulsive reactions in children, it was found that the sample group comprised 1.2 per cent of the total adult

and child psychiatric load, that there were equal numbers of boys and girls, and that the average age of onset was 7½ years. The group as a whole showed a better than average intelligence.

Etiology. Obsessions and compulsions of a minor kind begin early in life and persist through childhood. These disturbances are first seen in the elaborate bedtime and feeding rituals set up by the toddler, without which he cannot function comfortably. Rituals are frequently associated with rigid routines on the part of compulsive parents who, while not initiating the behavior, often seem to do their best to keep it going. A little later, obsessional fears, often recognized as unreasonable and absurd, lead to the use of magical counter-measures and are continued still later in the form of obsessional "games" such as the avoidance of cracks on the pavement ("Step on a crack and break your mother's back!").

According to psychoanalytic theory, obsessions are the consequence of release of repressed instinctual impulses and wishes from their unconscious representation; the released elements are then transferred to the sphere of consciousness in conjunction with some idea or set of ideas that has no presumptive relationship to the unconscious impulse, so that the child is unable to understand why he should be obsessed in this way. The reaction is interpreted as a defense against aggressive and sexual impulses particularly in relation to the Oedipus complex. The initial defense is by regression to the anal-sadistic level, but the impulses at this level are also intolerable and must be ward off by reaction formation, isolation, and undoing. Because the use of these defenses renders superfluous the use of repression proper, the offensive impulses can exist in consciousness, although when they do, they are divorced from their affective significance and so remain meaningless to the patient.

Because of the familial tendency, several investigators have assumed a specific constitutional predisposition, and terms such as "ideo-obsessive constitution" and "obsessive psychopathic constitution" are defined as an inherent tendency towards an abnormal persistence of responses in conjunction with autonomic lability. The child rearing of obsessional parents is rigidly scheduled, and the child is brought up with what Kanner refers to as "an overdose of parental perfectionism." The child learns early that strict adherence to what he is taught is "right" and to do otherwise is "wrong." The child's world is inevitably clean, neat, and orderly, and it is equally inevitable that the child of such an environment develops "just so" attitudes. It is not clear to what extent obsessional neurotic and personality disorders can be related to difficulties in sphincter training, nor are there any conclusive research findings to confirm or refute the connection. An investigation of 5-year-olds showed no behavioral differences in those who had been trained early or punitively, as compared with those trained late and permissively. It is possible that the cause lies

not in a particular sphere, but in the total training experience given to the child, whereby every aspect of his developmental world becomes infused with inflexible concerns. Sullivan has pointed to "preoccupation" in childhood as a precursor to later obsessional development.

Children who develop obsessional neurosis in late childhood or adolescence have often exhibited a variety of symptoms during the course of their development. These include phobias (40 per cent), hypersensitivity (35 per cent), anxiety (32 per cent), inhibitions (25 per cent), obsessiveness (22 per cent), shyness (20 per cent). Eighty-three per cent of such children can be regarded as "nervous." In contrast to the extroverted personality of the hysteric, introversion is found more commonly, although it is not marked prior to the onset of the illness.

The premorbid personality has been investigated from the psychoanalytical and clinical points of view. Clinicians, describing the obsessional personality, have pointed to the cautious, deliberate, persistent, conscientious, dependable, dogged, austere, and perfectionistic person, whereas psychoanalysts, elaborating on the original anal-erotic triad of Freud (orderliness, frugality, and obstinacy) have emphasized the stubbornness, egocentricity, and inflexibility of the person in general, and in particular portray such individuals as tyrannical, power-loving, dictatorial, hypercritical, vindictive, avaricious, parsimonious, irritable, malcontented, and hypochondriacal. The positive and negative pictures also seem to depend on the degree of adjustment shown by the obsessional individual, whether his management of his life situation indicated a successful or unsuccessful obsessional. If the child is doing well at school, his ambitious and intellectual parents will be inclined to treat his obsessional traits with respect, whereas the child with a school problem may be described in similar terms, but the wording of the complaint will be more negatively phrased.

The classical triad may exist in different proportions. In a typical group of obsessional cases, 72 per cent will be orderly, 4 per cent disorderly, and 24 per cent in between; 50 per cent will be frugal, 6 per cent extravagant, and 44 per cent in between; 40 per cent will be obstinate, 20 per cent compliant, and 40 per cent in between. There is a tendency for some children to maintain "leakage" symptoms, so that they show dirtiness, disorderliness, and compliance in the setting of a "perfect" obsessional personality. This is especially characteristic of certain cases of encopresis in which a scrupulously clean child will show a psychological "leakage" in addition to his physical leakage.

As in the case of the Rat Man, the child begins his obsessional illness with the emergence of unacceptable thoughts, sometimes blasphemous, sometimes sexual, and sometimes aggressive. He may try hard to think of something else and shake off the disturbing thoughts, sometimes even literally by means of tic-

like movements. Unlike the adult obsessional, the child usually cannot keep his thoughts or ruminations to himself and may force his parents to participate in his rituals, answer his repetitious questions, and cater to his obsessional wants as punctiliously as he does himself. The mother's compulsions may not fit those of the child, and she consequently tends to become increasingly impatient with his insistence and may attempt to turn him aside from his demands, first by reason and argument and finally by punishment, so that child and mother are soon locked in an interminable "somasochistic battle." The child finds himself caught between two wrongs: his unconscious wishes are "wrong," and his conscious defenses are also "wrong." Invariably, anxiety and depression may supervene, together with vague psychosomatic symptoms of various kinds.

Differential diagnosis. These disorders must be distinguished from normal, compulsive rituals of the toddler around training situations, or the obsessional "games" of the early school child carried out in the service of mastering aggressive impulses.

Prognosis. Recent studies of the natural history of obsessional neurosis as it extends through the lifetime of the individual seem to indicate that the prognosis is not as unfavorable as was once thought and that spontaneous remissions are fairly frequent. The factors influencing prognosis in an unfavorable direction are existence of obsessional symptoms in early childhood, the occurrence of a premorbid obsessional personality, the occurrence of obsessional acts, and a severe clinical picture on first admission. Although obsessional symptoms starting at about 6 years of age may clear up spontaneously in 1 or 2 years (see Wolf Man), Kan-ner has stated that he has never known pathological obsessions of children to subside without outside therapeutic help. Sometimes the obsessional symptoms subside, but the background of anxiety, sensitivity, and inhibition may remain with the result that the child continues to be "nervous." Sometimes, the child may begin to hide or camouflage his symptomatic acts. The prognosis, with treatment, of childhood obsessional states is fairly good, especially after prolonged, intensive psychotherapy. About 30 to 40 per cent of the cases become completely free with another 40 to 50 per cent "much improved" or "improved." About 10 to 15 per cent of the cases apparently do not improve (the adult cases do less well if one takes the average of five well known studies: 27 per cent are free of symptoms, 37 per cent are improved, and about 36 per cent remain static or grow worse).

Management. Therapy with an obsessional child takes place in a series of stages. In stage one, the child is relieved to talk about his peculiar symptoms without being mocked, criticized, or punished; within this therapeutic setting, he is enabled to bring his whole repertoire of symptoms into the open. He can also express his anger at the repercussions his illness brings about in his home environment. In stage two, the child

attempts to use the therapist in the same way he uses his mother, as a participant in his ceremonials, and, when the therapist balks at assuming this particular role, a stormy situation ensues. In stage three, which is often heralded by "freer" dream material, the child's defenses appear less inflexible, and a greater amount of "leakage" enters into the treatment. The stage that follows is characterized by messiness and aggression, and the child seems for a while to wallow in his regressions. As this stage abates (to the relief of the parents who are, at this point, constantly threatening to take the child out of treatment), frank oedipal wishes and thoughts begin to emerge, and from then on the treatment resembles that of other neurotic children.

Depressive Reaction

Definition. Psychoneurotic, depressive disorders involve internalized conflicts in relation to deeply ambivalent feelings and are not commonly seen in their fully developed adult form in children, although what have been referred to as "depressive equivalents" may take the place of the depression, varying in their composition with the child's stage of development. The conflict anxiety is said to be mitigated by self-depreciation and the sagging of mood. In older children, as in adults, a loss of self-esteem, associated with feelings of guilt and ambivalence toward loved persons have been reported. Psychomotor retardation and agitation are occasionally present, but are much less marked than in adults.

The fully developed depressive syndrome in the adult psychotic can be said to have three classes of symptoms: primary (sad affect, reduction of drive and productivity, and psychomotor agitation and retardation); secondary (feelings of helplessness, hopelessness, and worthlessness); and tertiary (obsessional reactions, hypochondriacal preoccupations, delusions and hallucinations, suicidal thoughts and tendencies). The neurotic reaction borrows a little from this general picture, although excluding the more malignant tertiary components and adding a neurotic conflict and neurotic personality to the clinical picture. The depressive reaction in children in turn borrows something from the neurotic depression of adults (the sadness, helplessness, loneliness, homesickness, and inadequacy) excluding, to some extent, the structured, internalized conflict in relation to ambivalence, and adding phase-characteristic depressive equivalents.

The difference between the child and adult picture can be attributed in part to the inability of the child to verbalize his affective state, to the incomplete development of the superego, and to the absence of consistent self-representation. The difference between neurotic and psychotic depression is that in the former, the individual attempts to force external objects to replenish his reduced "narcissistic supplies," and in the latter, the individual withdraws from and incorporates the unsatisfying object, attempting to reestab-

lish his self-esteem in the intrapsychic sphere. Many psychoanalysts have stressed the fact that the child, by virtue of his indispensable need for an object relationship, is compelled to direct his attention toward external, substitute objects. In addition, his weak superego prevents typical depressive clinging to lost objects in the form of protracted mourning, at the same time permitting replacements and substitutes. It does not encourage assaults on the ego in the form of self-reproach and pervasive pathological guilt. The rapid regressions of childhood also imply quicker restitutions.

The depressed child experiences a feeling of pain over real or supposed deprivation and may resign himself in a helpless, impotent way to the painful situation or react with aggression against the source of pain. The depressive response is always associated with undischarged aggression, and fear of superego sanctions leads to repression or displacement of the aggression onto the self. The defenses against the depressive affect are similar to those used to withstand anxiety.

When depression is carefully defined in adult terms, it is difficult for some investigators to acknowledge its occurrence before puberty. When the investigator is prepared to compromise with the criteria and accept the "depressive equivalents" in the child equally with depression in the adult, it is possible to regard certain clinical states, such as school phobias, as manifesting depression. It is generally agreed that transient, depressive feelings are frequent in childhood, but this does not represent a psychopathological state, and some clinicians have questioned whether "depressive equivalents" do not represent a potpourri of childhood psychopathology rather than the syndrome of depression.

Epidemiology. Bearing in mind the controversial nature of the evidence offered for the existence of this reaction as an entity, it is almost a hopeless task to attempt to ascertain its prevalence. The few studies in the literature are merely descriptive of a small number of cases.

Etiology. From an etiological standpoint, it would seem important to differentiate among psychotic depressions (which do not appear to occur during childhood), reactive depressions in response to loss (seen in anaclitic depressions, grief reactions, and in the rudimentary mourning of older children), and depressive reactions linked to neurotic conflicts. Within the framework of psychoanalytic theory, the nuclear conflict of the psychoneuroses would be expected to operate similarly in the case of the depressive reaction. The crucial question would then be that of the circumstances under which one would expect depression to ensue from the oedipal disturbance. The complex contains within it affects of fear and anxiety as well as reactions of guilt, love, tenderness, hostility, and aggression. It involves the fantasied loss of one or both parents, the renunciation of one or both parents,

jealousy, envy, and death wishes. In the face of competition with the adult, the child may experience strong feelings of inadequacy and inferiority.

There seems little doubt that the depressive reaction, when it occurs, must have a close relationship to the aggressive feelings directed toward the loved parent of the same sex, thereby generating a conflict of ambivalence. Even the resolution of that conflict and the preservation of the rival involves some degree of loss in the renunciation of the basic desires. It is not surprising that some children, "predisposed to depression," react to the dilemma with depressive feelings, the castration anxiety in such cases remaining relatively mild. Again, whereas many children awake from oedipal dreams containing death wishes in a state of great anxiety, demanding reassurance, these susceptible children continue to lie sadly in their beds, full of remorse and often weeping uncontrollably.

Clinical description. The depressive picture in children between 8 and 11 years includes the following characteristics: weeping bouts, some flatness of affect, fears of death for self or parents, irritability, somatic complaints, loss of appetite and energy, varying degrees of difficulty in school adjustment, and vacillation between clinging to and unreasonable hostility toward their parents. Self-deprecation is often marked. In appearance, the child may look sad and depressed, talk in a low, weak voice, turn his head to the wall, cry frequently, and constantly iterate his loneliness. Nothing appears to cheer him up, and he seems to have all the energy drained out of him. The precipitating factors are usually specific events such as accidents and physical illnesses but not the real loss of either parent.

Instead of depression, a child may present with "depressive equivalents," which can include eating and sleeping disturbances, antisocial behavior, accident proneness, running away from home, boredom and restlessness, fatigue, difficulty in concentration, and sexual acting out. These also represent modes of defense adopted to ward off feelings of depression, isolation, loneliness, and emptiness.

The occurrence of depressive feeling and depressive equivalents is not unlike the occurrence of free-floating anxiety and the anxiety equivalents before they have been counteracted by mechanisms of displacement, conversion, dissociation, etc. Objectless depression, like objectless anxiety, occasions a certain degree of perplexity, because the child is not sure why he is depressed when there are no current reasons for the response. With objectless depression, too, as with objectless anxiety, there exists a feeling that something unpleasant is going to happen in the future, giving rise to a sense of foreboding and doom coupled with pessimism.

The wish to die may stimulate suicidal ruminations, suicidal attempts, and actual suicide. There exists a great deal of untenable statistical data regarding sui-

cide in childhood. The figures are based on notified cases, and there is a growing belief that a number of cases are never reported or are disguised as accidents. It is not surprising that incidence figures not only vary from one report to the next but may be contradictory. Suicide is said to be rare under 10 (only three children reported in this group in 1958), varying between 35 and 60 each year in the age group of 10 to 14 years, and between 250 and 300 each year in the age group of 15 to 19 years. This is out of the total child population of the United States until 19 years. Girls outnumber boys in attempting suicide 3 to 1, and boys outnumber girls in successful suicide 3 to 1 (the proportion of attempted to successful suicide is approximately 100 to 1). In one study of attempted suicide in adolescence, it was found that 15 per cent had a previous history of major accidents, and 6 per cent had made previous suicide attempts. In 8 per cent the father was dead. In half the cases, there was no adult figure in the house at the time of the attempt, but in 29 per cent of the cases the mother was at home. One of the main causes given was the use of disciplinary measures giving rise to emotional upset and depression. The suicidal method most in favor was the use of drugs (aspirins, barbiturates, and tranquilizers). Some of the attempts at suicide seemed to be manifestations of risk-taking behavior.

The "core" factor in the formation of a suicidal personality in childhood is thought to be a loss of love, real and fantasied. The part played by depression may be relatively small (less than 7 per cent, although this may be related to the difficulty in recognizing depression below the age of puberty). In the adolescent, identity crisis may play the role that depression plays in the adult. The amount of psychosis found varies with the study but is thought to be small. However, in one study at the Payne Whitney Clinic, of 37 attempted suicides between the ages of 13 and 19, 23 were diagnosed as schizophrenic. The same study defines the suicidal adolescent as "an individual who is delusional in varying degrees, withdrawn, spending a considerable amount of time in fantasy activity, with little if any somatic complaints, but constructing a picture of supposed wrongs done to him by associates, parents, or siblings. He may show very little by way of overt anxiety and might or might not have complaints of feelings of depression." Impulsiveness may, on occasion, lead to suicidal attempts, but these are often ill conceived and therefore likely to be unsuccessful. In the younger group, there may be a real physical difficulty in bringing off a successful suicide. Occasionally, a child may imitate a suicide seen on TV.

The psychodynamics underlying suicidal attempts include an appeal component representing a plea for help in dealing with sexual difficulty and hostile impulses aimed at the parents. According to Zilboorg, suicide at puberty is more often a primitive urge resulting from frustration of genital wishes rather than

an oral-aggressive one. Both intrapsychic and interpersonal conflicts of a serious nature are present in all suicidal attempts in children, most patients demonstrating long-standing, unrecognized disturbed mental states. These are usually associated with disturbed family relations and most frequently rejecting or highly ambivalent mothers. The immediate motives are usually multiple and include anxiety over school work, problems revolving around sexuality and social adaptation, and frequently some experience interpreted in terms of loss.

Differential diagnosis. Depressive reactions must be differentiated from acute reactive disorders (grief), anaclitic depressions, transient depressive feelings in developmental or situational crises, cyclical mood swings occurring in developmental disturbances, and psychotic depressions seen in adolescents with a schizoaffective disorder.

Prognosis. The predisposition to depression is occasionally so strong that the individual responds to all difficulties (frustrations, deprivations, losses) with depression. Klein has postulated a "depressive position" in the 1st year of life, and Abrahams a primary parathymia in the preschool child, as precursors to later depressive elements. The individual with such a depressive personality tends to face problem-solving situations with the expectation of becoming depressed. This is again equivalent to the anxious or stress sensitive personality.

Symptomatic treatment, aimed at relieving the child's mood, is usually effective but offers no safeguard against the occurrence of similar reactions in the future, unless the underlying neurotic conflict is also resolved and some measure of insight furnished to the child.

Management. As with the other psychoneurotic conditions, intensive psychotherapy is the treatment of choice for the depressive reaction. Antidepressive drugs, such as amitriptyline (Elavil), may be indicated when the phenomenological picture is similar to the depressions of adult life with marked loss of self-esteem, withdrawal from social interaction, depressive affect, self-accusation, and self-deprecation. In cases of attempted suicide in children, it is better to hospitalize the patient for a period following the attempt. Tranquilizers and antidepressants can be used as adjuncts, but the therapeutic aim should be insight rather than reassurance, since it is important for the patient to develop some understanding of his unsatisfied needs and the way in which his suicidal attempt relates to the unconscious motivating forces. It has been suggested that, during this critical period, the psychiatrist should make himself more easily available to the child and prescribe the frequency of the therapeutic interviews in relation to the child's needs.

Suggested Cross References

The neurotic disorders are also discussed in Chapters 23 and 24 in Area F, which deals with the psy-

chiatric disorders of adults. For a more detailed description of classical psychoanalytic theory, which underlies this discussion of neurotic disorders of children, see Chapter 6 in Area C, on current concepts of personality and psychopathology. This area also contains descriptions of alternate conceptual models of personality development and symptom formation. Suicide is also discussed in Section 33.1.

41.2 PSYCHOPHYSIOLOGICAL DISORDERS

STUART M. FINCH, M.D.

Definition

Psychophysiological disorders in children, like those in adults, are defined in the American Psychiatric Association standard nomenclature as conditions in which "the symptoms are due to a chronic and exaggerated state of the normal physiological expression of emotion, with the feeling, or subjective part, repressed. Such long continued visceral states may eventually lead to structural changes." This definition, now some years old, is really an oversimplification of an extremely complex set of disorders. The term "psychophysiological disorder" is best reserved for a diverse group of conditions in which both psychic and biological factors play a role in producing a somatic disorder. Typically, such diseases include obesity, bronchial asthma, eczema, and ulcerative colitis. In these conditions there appears to be a biological factor, often only partially identified, which in combination with certain psychopathological stresses leads to the development of a particular syndrome.

The term "psychophysiological" as used today replaces the older terms of "organ neurosis" and "psychosomatic disorder." This area of medicine, however, remains vague and ill defined, and just how many disease entities can properly be included in this broad term is as yet unclear. Modern research has shown that many illnesses previously thought to be purely infectious or degenerative have emotional aspects. Even vulnerability to the common cold appears to have a relationship to emotional tensions. This section discusses only those conditions that have gradually come to be considered typical of the psychophysiological disorder group.

Anorexia Nervosa

Definition. Anorexia nervosa is a serious and sometimes life-endangering condition characterized by a self-imposed, severe dietary limitation, leading to extreme loss of weight, malaise, and other associated symptoms and serious malnutrition.

Clinical description. Although it is most common in young adults, anorexia nervosa can occur at puberty or even before. The most typical history is that of the slightly obese youngster who decides to go on a self-imposed and often severe diet. The decision may be based on some small incident where the youngster was criticized for his obesity or awkwardness. The child and his parents are often pleased with the resulting weight loss until it becomes excessive, at which point efforts to encourage the child into a more rea-

sonable intake are found to be futile. The common sense approach to the child in terms of the need for a certain number of calories, vitamins, etc., seems useless. The child becomes increasingly malnourished and gaunt but clings to the idea that he is improving his health.

A 12-year old may begin such a diet at 115 pounds and continue to lose weight until he is perhaps 60 pounds, by which point his entire body physiology is extremely disturbed. He may continue with exercises, again of a self-imposed nature. Restlessness is common in these youngsters, and that intensifies the physiological difficulty.

The diagnosis of anorexia nervosa is made on the basis of the excessive weight loss combined with the history of the peculiar dietary limitations the youngster has imposed on himself. As the malnutrition continues, the youngster becomes increasingly cachectic, but in spite of his general physical weakness he often continues with body-building exercises. Body reserves are generally used up. Blood sugar drops, and the youngster may suffer a circulatory collapse. It is essential in making the diagnosis to rule out any other cause of anorexia and subsequent weight loss. An undiscovered malignancy or infection, for example, may simulate anorexia nervosa.

The premorbid personality of the youngster with anorexia nervosa is usually one of a constricted, compulsive, rigid type. Hypersensitivity is a very common characteristic, and some of these children have schizoid traits. Both oral and anal residual qualities are usual. Once the disorder has developed, the child devotes a great deal of time and thought to the whole subject of food. In spite of learning the caloric content of foods and the requisites of an adequate diet, the child continues to eat very little—far below the requirement for normal health. The mechanism of denial is extremely prominent in these youngsters. They will claim to feel physically fine when it is obvious that they are so weak they can hardly stand or walk. They can even look in a mirror and remain oblivious to the fact that they are seriously malnourished. Bribes and threats by family or physician aimed at getting the youngster to eat more are usually fruitless.

It has been postulated that the psychodynamics of the anorexic child involves the entanglement of sexual and aggressive instincts with the concept of food intake. These basically immature youngsters fear growing up. Eating becomes a destructive oral aggressive act, one that also has sexual connotations. Unconsciously, to eat is to grow bigger, more aggressive, and more sexual. In attempting to ward off such dangerous instinctual impulses, the child also wards off eating.

The parents of children with anorexia nervosa present no uniform type of psychopathology. Most of these youngsters have probably been overprotected by

one or both parents. As with most other psychosomatic disorders, the child has had a close and markedly ambivalent tie to one parent or the other. The disorder tends to occur somewhat more commonly in girls than in boys, but the close ties exist between either parent and children of either sex. By the time the disorder is well advanced, one parent, if not both, has usually become extremely overconcerned and oversolicitous and may spend long hours bribing, threatening, and otherwise attempting to get the child to eat.

Psychophysiology. Anorexia nervosa is a non-classic psychophysiological disorder in which it is difficult to postulate the existence of a biological factor. Most of the symptoms of this disorder can be explained on the basis of severe psychological difficulties, which result in a marked limitation of nutritional intake. The subsequent physiological results are those of ordinary malnutrition—loss of weight with all the concomitant secondary factors associated with severe malnutrition. The end result of self-imposed starvation is physically the same as if a child was subjected to involuntary starvation. Once the child begins to eat again, all these physical problems disappear. When a child does recover from anorexia, however, there is apt to be a swing back toward obesity, which probably does include a biological factor.

Management and prognosis. As with children suffering from other psychophysiological disorders, the youngster with anorexia nervosa is often not recognized as having a serious psychological difficulty until the physical symptoms are well advanced. They are usually children who have been regarded as well behaved and even well adjusted. They may have done well academically and have presented no management problems to their parents. Only closer observation reveals the past hypersensitivity, marginal social adjustment, and compulsive features. One of the first requirements of the effective management of these children is convincing the parents that there is a large psychological contribution. This may not be particularly difficult during the middle and advanced stages of the disorder, when they see the child's peculiar and distorted view of his food intake and his insistence that he is in good health. Parents can be helped to understand that the youngster is physically healthy in terms of the absence of any organic disease. They need to understand that the child's symptomatology is emotional and the result of his own attitude toward eating.

Enlistment of parental cooperation in the total treatment program is vitally essential, whether the child is to be treated as an outpatient or in a residential center. By the time the disorder is well developed, considerable secondary gain has usually been added. All parental efforts toward enticing or threatening the child into eating must be discontinued, and the child

must be convinced that his dietary intake is totally up to him. This attitude must also be developed in any other important adults involved in the treatment process, including the local family physician, relatives, and hospital personnel. The child is in a chronic battle with all those who would make him eat, and it is essential that this battleground be removed.

The treatment approach to the child himself is that of relatively forceful and active interpretation of what is going on and to some extent why. He must be helped to understand not only that his dieting is excessive and harmful to himself but also that it is based on his unwillingness to grow up. The extensive use of denial by the child as a mechanism of defense means, as a rule, that therapy cannot succeed unless this particular mechanism is met head on. Some therapists feel that better results are obtained by granting the child's wishes and allowing him thorough, total oral regression, which is thought by some to underlie this disorder. Others find that this does not work nearly so well as facing the child with reality, challenging his use of denial, and actively pushing him toward acceptance of some of the duties and responsibilities appropriate to his age group. The child's nutritional intake must be detached from his aggressive and sexual struggles while these other problems are dealt with. He should be helped to understand how he is using food in an attempt to find a solution to difficulties he has feared facing.

It sometimes becomes necessary to feed the patient intravenously or by nasal tube. If such measures become necessary, the child must be helped to understand that he himself has caused the situation and that the measures undertaken are not provoked by hostility on the part of the physicians but are practical requirements of the circumstances. When the child begins to face what he is doing, these treatment procedures become unnecessary.

Neither excessive concern about the child's physical health nor a sadistic approach are of value. The general therapeutic approach, at least in the beginning, is a matter of fact accounting of what the youngster must have in the way of food intake, plus reassurance that, if other problems are present, they may be discussed. In the meantime, food intake must remain at a specified level, and weight gain must take place, or the involuntary feeding will, of necessity, be introduced. Once the patient has begun to divorce his eating from his other difficulties, his physical status begins to improve, and his emotional problems can be worked on in a more leisurely and classical fashion.

Obesity

Clinical description. Obesity in childhood is much more difficult to describe accurately than it is in adulthood. The fat baby and the chubby toddler are commonplace and do not necessarily qualify as obese children. In general, obesity in youngsters begins to

be diagnosed as a recognized and clearly defined syndrome during the grade school years. At this time, the obese child is one whose weight reveals him to be excessively heavy for his age and his height. The obesity may have been present during infancy and remained throughout grade school and into adolescence. Or it may begin later in childhood or even in early adolescence. The classically obese child has an obvious excess of adipose tissue.

The obesity itself is apt to interfere with the child's participation in normal childhood activities, particularly in athletics. Taunts from other children further isolate the obese child, who turns increasingly to eating and less to ordinary physical activities. Sensitivity about obesity tends to become enhanced at puberty. At this time, many of these youngsters begin to take dieting more seriously. Also, families tend to pay less attention to obesity during prepuberty than at adolescence.

From a statistical standpoint, obesity in children is more prevalent when they have obese parents. It is commonly observed that obese children are jolly on the surface, but unhappy inside, but this is not invariably so. Some obese youngsters are reasonably well adjusted, in spite of their obesity. Others are sensitive, selfish, and without friends.

Psychophysiology. Obesity, like most other psychophysiological disorders, is only partially understood. The overeating that results in obesity may arise from any one of several causes or combinations of causes. Certainly, some children become overweight because of purely endocrine difficulties. Such cases are relatively rare and are usually identified by a thorough physical examination. The remaining obese children, the majority of them, are not a homogeneous group. It is often difficult to determine whether the obesity is at least in part genetic or is due primarily to a family pattern of overeating.

The work of Bruch suggested that perhaps a majority of obese youngsters have developed this condition as a result of perpetuated and exaggerated oral needs. The orally oriented individual has great needs and demands much from his environment. He may sometimes have his needs met by excessive love and attention; at other times he may seek to meet them by an increase in caloric intake. Bruch's studies have indicated that many obese children come from families in which food is overvalued. Mothers who themselves are oral in nature tend to feed the infant whenever he is uncomfortable, regardless of the reason for his discomfort. The young child builds a pathway from need to eating. He remains oral, dependent, and insecure; as a result, he is often uncomfortable. He attempts to satiate himself through eating and, as a result, becomes obese. He often has little if any motivation to diet because there are no other routes through which he can meet his oral needs.

It appears that there are genetic, constitutional, biological, and psychological factors contributing to

the hyperphagia that results in obesity. Certain children, although obese, are not particularly maladjusted, and their obesity can be kept under control without great difficulty. The over-all picture presented by each child requires considerable attention to each of these factors.

Management and prognosis. Obesity in a youngster is not generally considered a life-endangering or even a serious disorder. Parents may occasionally bring a child to a physician because of obesity, but more often than not this condition is recognized by the physician, and it becomes his responsibility to suggest a course of treatment. Frequently, the child and his parents have been aware that he is overweight, but they have either accepted this as part of the family pattern or assumed that it would eventually disappear.

Proper management of the obese child involves a thorough study of the family and of the child himself. If the family tends toward overweight and the youngster's obesity is not excessive, little if any therapeutic measures may be necessary. If, on the other hand, the youngster reveals the psychological characteristics typical of many obese children—immaturity, hypersensitivity, and insatiability—more stringent therapeutic measures may be necessary.

Bronchial Asthma

Definition. Bronchial asthma is a condition characterized by recurrent episodes of a wheezing type of dyspnea with labored and prolonged expiration. Attacks of asthma may be brief and mild or severe and prolonged, reaching the stage of status asthmaticus. The symptoms are due primarily to a narrowing of the smaller bronchi and bronchioles. Although the condition may occur at almost any time in life, it often originates during the childhood years.

Clinical description. The child with bronchial asthma is subject to recurrent attacks of wheezing dyspnea, which may come on as a result of exposure to a particular allergen, during a period of emotional stress, or without apparent reason. The attacks may last from a few minutes to several days. The labored breathing may be mild or may reach the point where the child needs the assistance of an artificial respirator. The attacks may be seasonal or not.

An attack of bronchial asthma is physically uncomfortable and produces anxiety in the child as well as the parents. Medical advice is usually sought early, and the diagnosis is relatively easy, based on the characteristic wheezing respirations and the prolonged expiratory phase, with prominent rhonchi and rales. If the condition persists over a number of years, there is a tendency for the youngster to develop emphysema, with a diminished vital capacity.

As soon as the diagnosis is established, the average physician begins to search for the allergic factors that he assumes are responsible for the attacks, scheduling a series of skin tests and taking a careful his-

tory in an attempt to narrow down the search. Although it is sometimes possible to find specific allergens that produce the attack whenever the patient is exposed to them, at other times such a search is fruitless.

Physicians have long known that children with bronchial asthma frequently reveal overt emotional difficulties. Some physicians tend to attribute this to the asthma itself, but others feel that it is a contributing cause. Probably both factors are involved. Emotional factors do contribute to asthma in many youngsters, and the child with asthma is also prone to develop additional emotional problems as a result of his condition.

The characteristic course of asthma during childhood is extremely varied. Sometimes it begins very early in life and continues throughout childhood into adult life. At other times it begins late in childhood, lasts a short time, and then becomes quiescent. Serious cases usually start during the preschool years and become increasingly incapacitating as the child grows older.

As a result of repeated asthmatic attacks and the additional limitations imposed by medical management, many of these youngsters lead relatively secluded, quiet lives. They miss the opportunity of mingling freely with their peers. They are often forbidden athletic opportunities. They may be put on limited diets and be subjected to long term desensitization procedures. Asthmatic children often have other psychosomatic difficulties, such as eczema and other skin problems.

Psychophysiology. Asthmatic children can be broadly divided into two groups. One group contains those youngsters who show a number of neurotic symptoms and relatively few strong allergic reactions. These are children who respond well to residential treatment in special homes for asthmatic children. They do not tend to become steroid-fast, although they may originally react fairly well to steroid treatment. The other group of asthmatic children show fewer neurotic symptoms and less improvement when separated from parents and placed in a residential treatment center. They are prone to remain steroid-fast—that is, they do not tolerate removal of steroids, and if this is attempted, they redevelop their asthmatic symptoms.

The theories developed over the years regarding the psychological contributions to asthma in children have been numerous and conflicting. They have included the concepts that the asthmatic dyspnea represents a repressed cry of the infant for the mother, the perpetuation of an early mother-child ambivalent tie, the perpetuation of various anal features due to strict toilet training, and an over-all emotionally deprived early infancy and childhood. It seems impossible at this point to present any well documented, proved, and unchallenged theory as to the psychological role in the production of asthma. It is not even possible to delineate certain types of personality structure in asthmatic children, as some authorities claim is possible

in ulcerative colitis, for example. Asthmatic children may, and often do, have other psychosomatic difficulties including eczema, ulcerative colitis, rheumatoid arthritis, and migraine. They may be neurotically oriented children or have severe characterological problems. Early in the investigation of the psychological aspects of asthma, it was felt that these youngsters were by and large more intelligent than the average, but subsequent studies by Schneer have proved that this is not so.

At the present time, one can only say that various psychological factors may be involved in the production of asthma. These factors may be more important in some children than in others. It should also be kept in mind that an asthmatic attack is a psychologically traumatic event. Inability to breathe has life-threatening aspects and is bound to produce anxiety. The possibility of a subsequent attack may well reactivate the anxiety and assist in producing a new attack. The surrounding adults who themselves become increasingly anxious only serve to intensify the child's anxiety.

Management and prognosis. The child with bronchial asthma deserves, as does any other youngster with a serious chronic disorder, a complete physical and a psychiatric evaluation. Such a total study often gives important clues to the biological and psychological factors involved, thus allowing appropriate therapeutic measures. Some youngsters do not respond well to psychiatric measures and present a lesser amount of psychopathology. The immunological and autoimmune factors appear to be predominant in these children. In other youngsters, the neurotic features are more prominent, and environmental manipulation and psychiatric treatment are more effective. There are, of course, children with combinations of both; for them, total team management is essential.

Residential centers for asthmatic children are located primarily in the West and Southwest parts of the United States, and it was originally assumed that their greatest benefit stemmed from the climate. Although this may be important in certain cases, the concomitant "parentectomy" may be even more crucial in others, where separation of the child from his family psychopathology leads to marked improvement in the asthma, even without medication or other therapeutic measures. The children most apt to benefit by this environmental manipulation are those with more neurotic features and fewer allergic problems.

The psychiatric treatment of asthmatic children is not particularly unique. It is based on the neurotic or characterological problems the youngster presents. As with most other psychosomatic problems, it is essential to have a good working relationship with the other physicians involved in the treatment of the child. Many nonpsychiatric physicians, although aware that emotions may contribute to asthma, do not have a thorough understanding of the importance of the child's psychodynamics and the family psycho-

logical interactions. They may not recognize the importance of the emotional impact of some of their own advice to the family and how this can be distorted by both parents and child. For example, increasing limitations placed on the youngster's food intake, drastic curtailment of activities and socialization, getting rid of all pets, and total revision of household management and cleaning can at times be useful, but they may also produce almost as many problems as they cure. If the nonpsychiatric physician understands family dynamics, he may modify his approach and yet still accomplish his therapeutic goals.

Treatment of the child's parents is essential when the youngster's emotional difficulties are predominant. Also, some therapeutic assistance to parents is usually necessary when the child's asthma is primarily of an allergic nature. In the first instance, the treatment is directed toward the underlying emotional problems of the parents, as they may affect the emotional maturation of the child. In both instances, it is necessary to help the parents deal realistically with the asthmatic child, so that they neither overprotect nor reject him. Secondary gain accruing to the child from his asthmatic attacks should be minimized. All possible physical activities should be encouraged whenever they are not contraindicated by the asthma itself. The tendency for parents to infantilize such youngsters is common and must be minimized. It is often a matter of delicate judgment as to what physical or social limitations need to be imposed on these children. Such judgments are best reached by the team of physicians, all of whom should be thoroughly acquainted with all aspects of the child's family and his disease.

Functional Constipation

Definition. Functional constipation may be defined as a chronic condition due primarily to emotional problems in which the bowel is evacuated only at long intervals and with difficulty. The child with this disorder characteristically has a bowel movement only every several days and, often, only with the help of suppositories, laxatives, or some stool-softening agent.

Clinical description. A typical history of the child with functional constipation reveals that his difficulty began early, usually during his 1st year and invariably by the 2nd or 3rd year of life. The child seemed, according to his parents, not to have a daily bowel movement as they wished but occasionally to skip a day or two. This was followed by parental manipulations designed to produce a daily movement. Slowly, over a period of months, the child became increasingly recalcitrant about evacuation, and the parents increasingly concerned. They began to take additional measures to produce the bowel movement they thought necessary each day, since the child seemed unable to do so without parental interference.

By the time a youngster has reached school age with this condition, he is often quite constipated, his parents have proved to themselves and to the physician that, if left to his own devices, he will not have a normal bowel movement for 3 or 4 days, perhaps even longer. As a result, the parents have often instituted a regimen of suppositories, enemas, or mineral oil. The evacuations the child does produce may, if infrequent, be large and perhaps even painful.

The diagnosis is made on the basis of the history of infrequent bowel movements, a parent-child conflict over the production of bowel movements, and the demonstration of a potentially normal colon. The last includes the ruling out of Hirschsprung's disease, which is a megacolon due to a faulty innervation. The latter condition is relatively rare but may require a colon biopsy in order to confirm the diagnosis. It is, of course, quite possible for a child with Hirschsprung's disease to become involved in a parent-child battle similar to that seen in the child with functional constipation. There is a general atonicity of the bowel in both conditions. The fecal mass tends to build up, and there may be leakage around the main fecal mass, producing mild soiling in the child.

It is safe to say that the majority of cases of chronic constipation in children result from emotional problems rather than neurological problems. A careful history usually elicits early toilet training difficulties and the fact that at least one parent has been overly stressful about daily bowel movements. Once the child begins to resist parent demands and withhold feces, an atonic colon that performs poorly tends to develop. Such an atonicity is further enhanced by parental use of laxatives, enemas, and suppositories. Too much parent-child interaction begins to focus around the child's habits of elimination. The administration of enemas holds a mixture of fear and pleasure for the child. A child with functional constipation presents a mixture of passive-aggressive rebellion toward parental demands and an atonic and poorly functioning colon.

Psychophysiology. This condition stems for the most part from overly intensified parental attempts toward early bowel training. Children with functional constipation have literally chosen to resist parental demands by not giving the very thing the parent seems most anxious to receive—a bowel movement every day. The personality of one or the other parent may be predominantly anal in nature, leading the parent to focus on the child's bowel habits in a demanding and forceful way. Such parents are often convinced of the potentially dire results of constipation, thus rationalizing their frequent intervention. The children with functional constipation may present predominantly anal characteristics, being obstinate, ambivalent, and generally passive-aggressive. Some of them present an overtly characterological passive-aggressive attitude; others become, at least by grade school age, predominantly compulsive. In both cases, however, the child's basic orientation is one of resistance—not only in

bowel habits but in other areas. Although those who have become compulsive appear less resistant and obstinate, these characteristics are basically present.

Constipation is one of the psychosomatic disorders that have relatively little of a biological nature contributing to the basic etiology. It appears that almost any child can be coerced into functional constipation by an overly demanding parent and that preexisting or physiological deficiency need not exist in the lower gastrointestinal tract to result in this condition.

Prognosis and management. The prognosis of functional constipation in childhood depends both on the age at which it is recognized and treated and on the degree of psychopathology within the parent and child. In general, the earlier the condition is diagnosed, the easier it is to treat. Treatment requires that the parents be helped to understand the degree to which they are preoccupied with the child's regularity of bowel movement. It is usually necessary to support and reassure parents during the early stages of treatment so that they will be able to give up their excessive demands on the child. As soon as the patient becomes convinced that his elimination is not of tremendous importance to his parents, he will become more regular. However, most youngsters with functional constipation also have many other anal characteristics, which may also need treatment.

It may be useful in the beginning of treatment to prescribe regular doses of mineral oil or some other stool-softening agent in order to prevent painful defecation. Both parents, however, must recognize the need for removing their attention from this physiological function and for allowing the child to assume such responsibility himself.

Ulcerative Colitis

Definition. Ulcerative colitis is a serious chronic condition characterized by recurrent episodes of severe, bloody diarrhea. It is accompanied by anorexia, weight loss, and anemia. There are characteristic changes in the mucosa of the lower bowel and occasionally in the terminal ileum.

Clinical description. Ulcerative colitis may occur at any time during the life span and has even been reported in neonates. The disease may develop in a child gradually, with one or more mild attacks that go unrecognized, or it may develop in a fulminating form that is fatal in a period of a month or two. Most characteristically, the patient develops diarrhea with up to 40 stools a day in which there is excessive mucus and varying degrees of blood. He loses his appetite, complains of cramping abdominal pains, and becomes listless and apathetic. An individual attack of ulcerative colitis may last from a few weeks to a few months, following which the symptoms may abate but rarely disappear entirely. Further attacks tend to occur when the child is under some type of emotional tension.

The child with chronic ulcerative colitis usually re-

mains somewhat anemic and underweight. If the condition persists for years, the child's growth may be seriously affected. Acute attacks of colitis carry with them the dangers of exsanguination or bowel perforation. Another complication of long standing ulcerative colitis in both children and adults is the higher incidence of carcinoma of the bowel.

The diagnosis is made on the basis of the history and of x-ray and sigmoidoscopic examination of the bowel. The colon mucosa is friable and bleeds easily. Ulcerations may or may not be visible on sigmoidoscopy. Pseudopolyposis is common. The disease may affect any or all of the lower bowel and at times extends into the distal portion of the ileum.

It has been suggested that children with ulcerative colitis can be divided into two relatively distinct personality types. By far the most common are those with obsessional personalities. The typical history reveals that the child has been perfectionistic, rigid, and overly conscientious. This pseudomature adjustment has been interrupted occasionally by brief episodes of infantile dependent behavior. Many of these youngsters have a history of peculiar eating habits, with intense dislikes for certain foods based on their consistency or color. There may also be a history of constipation, with occasional periods of mild diarrhea. When the child develops an attack of ulcerative colitis, he characteristically becomes whiney, depressed, and demanding; he generally withdraws from most of his ordinary activities. The depression in these children is quite prominent, and preoccupations with death are not uncommon.

A smaller number of children with ulcerative colitis have a personality quite different from that outlined above. They are querulous, demanding, manipulative children. These youngsters are somewhat less apt to develop acute fulminating attacks of colitis. Their symptoms are somewhat less dramatic but more constant. They often use the colitis in a manipulative fashion, to force parents and others to meet their excessive demands.

The parents of children with ulcerative colitis present more than the average amount of psychopathology, but there does not appear to be any single type of family dynamics characteristic of this disorder. One often finds a close, ambivalent, and almost symbiotic tie between the child and one of the parents.

Psychophysiology. Ulcerative colitis, like many other psychophysiological disorders, has been studied more thoroughly in adults than in children. One can probably assume, however, that similar factors operate regardless of the age of the patient. The most promising current research in ulcerative colitis appears to point in the direction of autoimmune factors. It has been demonstrated that the peripheral circulating blood of the patient with ulcerative colitis contains some as yet unidentified substance that is toxic to colon cells. Two basic questions remain unanswered. One has to do with the specific antigen in the blood

and its exact location, and the second has to do with the original triggering device that sets off the attack of colitis. One can presume, but as yet not prove, that emotional tension is the original triggering device. It is often, but not always, possible to demonstrate some type of emotional crisis surrounding the onset of colitis. It is also presumed, but as yet not proved, that, once the process begins, the reduction in emotional tension does not necessarily lead to a remission in the disease. Psychiatric improvement may not be followed by a similar improvement in bowel pathology.

Management and prognosis. Children with ulcerative colitis have, over the years, been treated by a variety of methods. Whenever this situation prevails, it is a probable indicator that the disease in question is not understood—and this is certainly true with ulcerative colitis. Currently, management of the child with this disease usually involves some dietary restrictions, particularly during an exacerbation of the disease. Iron may be prescribed to combat the anemia, and, if the latter becomes serious, transfusions may be necessary. Some physicians rely on steroids, particularly during acute attacks, but there is always the danger of problems inherent in removing the steroids later. A considerable number of these children eventually come to surgery, where a one-stage or two-stage colectomy is performed. The timing of the surgery is important. Although the fatality rate is much greater than normal in those patients who have suffered severe bleeding or perforation, one is reluctant to remove the colon from a child who seems to be getting along reasonably well. Once extensive, non-reversible changes have taken place in the bowel, it is probable that surgery will eventually have to take place. The incidence of carcinoma in such a diseased bowel increases after the passage of several years. Surgeons sometimes prefer to leave the rectal stump, particularly if it is not seriously diseased, in the hope of reanastomosis, thus ridding the youngster of a permanent ileostomy. Such reanastomoses in children are not frequent; of those that are performed, quite a number are unsuccessful because of a continuation of the disease in the rectal segment.

The most successful management of children with ulcerative colitis is based on a team approach involving a child psychiatrist, surgeon, pediatrician, and social worker. Each child and his parents are seen by all members of the team, and a joint decision is reached on the basis of the findings of each team member. There seems little doubt that psychotherapy for the child and casework for the parents are helpful in this disorder.

General Principles of Treatment of Psychophysiological Disease

This extremely complex group of disorders is at best only partly understood, without even general agreement as to which conditions should be properly classified under the category of psychophysiological

disorders. Certainly, in order to be considered as a psychophysiological disorder, the condition should have a strong emotional component. Most of these disorders also have a biological factor which may or may not be recognized. A great deal more research is needed to treat them more successfully and more scientifically than at present.

One should bear in mind that growing children are constantly changing, attempting to adapt. In most instances the parents at least consciously desire to have the physical problem eradicated but do not as a general rule perceive the emotional component. The majority of them do not see their own contribution to this emotional component and are not ready to accept help for themselves in order to cure what to them seems to be an obviously physical problem. Unfortunately, the viewpoint of many physicians is much like that of the parents. They are so busily engaged in treating the physical disorder that they deny appropriate attention to the psychological problems.

Psychosomatic personality. If one attempted to describe a psychosomatic personality in children, he would probably picture a relatively brittle, pseudomature youngster who in most instances pleases the adults with whom he comes into contact. He is a good child, a good student, and has not been a problem to anyone except with his occasional physical difficulties. When the psychosomatic disorder becomes really serious, he is apt to continue to be the good child and to impress most physicians as well as other adults as a well adjusted youngster. He may tolerate physical procedures well, even stoically, and his occasional infantile reactions are apt to be dismissed as normal by the physician. When it is pointed out that he has not adjusted especially well to youngsters of his own age, the parents or even the physician may reply that he has, after all, had some physical problems and, therefore, could not be expected to adjust well.

Management. In general, the management of a psychosomatically ill child may require the services of a team of not only physicians but members of other mental health disciplines as well. This need may be one of the chief barriers to the successful treatment of these children. The various specialists in medicine are not always able to work together in harmonious fashion, and where a psychiatrist is one of the predominant members of the team, continuing cooperation can become even more difficult. Nonpsychiatric physicians may be unfamiliar with and reluctant to work with such disciplines as social work and psychology, even though thorough and total communication between the various disciplines is essential.

A series of steps is necessary if a child with a psychophysiological disorder is to be treated with reasonable effectiveness. Step one is fundamental and involves the conviction of the primary physician that the disorder is psychosomatic. The average general practitioner has relatively little understanding of these disorders, particularly of their emotional psychic

elements. It is essential that he recognize the strong psychic component and that he be convinced that it is necessary to deal with this if the treatment is to be successful.

Step two, which follows naturally, is that this primary physician convince the child's parents that there is a large psychic element in the disease and that it must be taken into account in the treatment program. The physician can only do this if he himself is convinced not only of the importance of the psyche but also of the importance of the emotions in the production of this particular disorder.

Step three involves the enlisting of a team able to understand and undertake a therapeutic regimen for the youngster and his family. Such a team—comprised of a psychiatrist, a nurse, a social worker, and other professionals in various disciplines of medicine and outside of medicine—needs to understand the child's total physical situation and his emotional and intellectual status. They should also have a complete knowledge of the family and how their emotional reactions may have played a part in the disorder.

Making such a team operate smoothly is difficult. The time spent treating these youngsters and their families is great. In ulcerative colitis, for example, the surgeon may limit himself to removing the colons of those patients whose colitis has made this a necessary step, but if he is to be involved in the treatment both before and after colectomy, he will have to involve himself with a team of professionals working with the child.

The final step in working with these youngsters is the individual treatment of the child himself and the treatment of the parents. These youngsters should have the opportunity for regular psychotherapy while they are receiving adequate medical and surgical care. The parents often require extensive social casework to understand their own contributions to the child's illness and to alter his emotional environment.

Suggested Cross References

In this section, psychophysiological disorders of children were discussed largely from a conceptual viewpoint in which specific psychological factors are associated with specific disorders. For further information regarding fundamental concepts in psychosomatic medicine and discussions of alternate theoretical positions, see Section 29.3, on current concepts of psychosomatic medicine, and Chapter 30 on psychophysiological disorders of adults.

Personality Disorders

41.3 PATTERN AND TRAIT DISTURBANCES

JOSEPH D. TEICHER, M.D.

The Concept of Personality

Definition. Personality, or character, does not develop independently; nor is it an "accidental" phenomenon. Rather, it is determined, in large measure, by the interaction between the instincts and the environment. Personality refers to the individual's habitual patterns of behavior, the nature and design of which are unconsciously determined. More precisely, these patterns of behavior are the outward manifestation of the individual's inner interests and, in particular, his instinctual impulses.

No two individuals are identical in this regard. There are inevitable differences in instinct need and presentation. Secondly, there are differences in instinctual cathexis, in the intensity of instinctual drives. Clinical psychiatry is dedicated to the identification and description of the patient's unique pattern of instinctual functioning, for these data bring about an understanding of his mode of adapting to life, that is, of his personality.

Personality formation. Personality formation can best be described as a process of progressive integration: at each maturational stage, different psychological and physiological functions are coordinated to form dynamic patterns of behavior. The organization of primitive faculties and impulses in the infant can best be described as chaotic. Later, as the child learns to adapt needs to external conditions, these impulses and the faculties which permitted their expression and fulfillment are organized to form specific patterns of behavior. Because these patterns assure gratification of the child's basic needs, theoretically, at least, he is no longer completely dependent on the crucial adults in his environment. At the same time, however, the child's personality struc-

ture as a whole will reflect his responses to the conscious and unconscious components of his parents' personalities, and his perception of their conscious and unconscious attitudes toward him.

Concurrent with the formation of personality, the child develops a typical mode of behavior. Social and cultural factors may, of course, be expected to exert considerable influence on behavior. If this influence is to be a favorable one, the demands imposed on the child by the environment should not exceed realistic limits, and, above all, the environment must provide the child with adequate emotional support.

The determinants of personality. According to psychoanalytic theory, the dynamic forces which operate to produce the elements of personality determine the interaction between the instincts and the environment and, by implication, the regulation of instinctual expression by ego and superego. While the concept of instincts is generally accepted, their classification has long been the subject of controversy; nor is it likely that this dilemma will be resolved in the near future. Under the circumstances, it would seem most useful, for clinical purposes, to center this discussion on the child's uneven efforts in the course of his development to master his sexual and aggressive impulses.

The ego seeks to regulate instinctual expression to conform with the demands of the external world. In the early stages of development, the parents function as auxiliary egos and assist in the control of the instincts. Subsequently, parental dictates with regard to instinctual discharge are internalized to form the child's superego, or conscience. The superego imposes further controls on instinctual expression, insofar as violations of internalized parental values give rise to guilt feelings.

As the child develops, the ego and superego continue to mature and to influence his mode of behavior. At successive stages in his development, the nature of the child's instinctual expressions and his capacity to delay discharge, which depend, in turn, on ego and superego function, will determine personality structure. Viewed from this perspective, those factors which

may impair personality development emerge clearly. Just as there are individual differences in many constitutional givens, individual children may manifest wide differences in rate of ego development. The rate of ego maturation may also be affected by constitutional nervous system dysfunction. The controls exercised by the superego with regard to instinctual expression may be inappropriate, i.e., either too rigid or overpermissive, if the superego represents the distorted values of emotionally disturbed parents. The ability of parents, particularly the mother, to gratify the child's basic needs and thereby afford him a sense of security, and the specific mode of gratification, will play a crucial role in molding his earliest personality traits. As the child grows older, his expanding activities and contact with an increasing number of people will color his emotional functioning. At this point, his family, their modes of behavior and emotional expression, his peers, and the cultural milieu will all exert an influence on his development. In fact, however, the groundwork has already been laid: the child's potential level of personality organization and function is determined during the earliest stages of development.

Assessment of Psychopathology in Childhood

Nosology. Current diagnostic categories compound the confusing aspects of the clinical picture. The fact that the whole spectrum of psychopathology in childhood has been fitted rather forcibly into diagnostic categories adopted from the fields of adult psychiatry and criminology represents a major source of difficulty. Anna Freud has stated, in this connection, that this solution to the problems intrinsic to the diagnosis of personality pattern and trait disturbances in childhood has proven unsatisfactory as a basis for assessment, prognosis, and the selection of appropriate therapeutic measures.

Many authors have pointed out that, in contrast to later stages of development, it is more difficult to draw a line of demarcation between mental health and illness in childhood. During the early years of life, the relative strength of id and ego is in a constant state of flux; concomitantly, adaptive and defensive mechanisms, normal and pathogenic processes frequently merge. It has also been postulated that the transition from one developmental level to the next constitutes a potential psychological hazard, for it is at this point that major or minor stress is most likely to produce arrest in development, malfunction, fixation, or regression. Particularly when id impulses develop at a more rapid rate than ego functions, various factors may combine to undermine, distort, and deflect the forces on which mental growth is based.

As a general rule, current classifications of emotional disturbances have not contributed to our understanding of the etiology of specific disorders to any degree; nor do they facilitate differential diagnosis in a dynamic sense. Yet, unless the clinician is aware of

the underlying pathogenesis of an emotional disturbance, he cannot accurately evaluate the patient's presenting symptoms, assign them to the proper dynamic categories, or institute appropriate therapeutic measures. Diagnostic formulations which are primarily descriptive, which derive from superficial observation of overt symptomatology, may have disastrous repercussions when they are used as the basis for psychoanalytic inferences. Of particular significance for the classification of emotional disorders in childhood is the fact that current diagnostic procedures neglect such crucial variables as age and stage of development. Nor do they make sufficient allowance for the difference between symptoms which are due to the delay or failure to acquire and perfect specific personality traits, and symptoms which are caused by the breakdown of previously acquired functions or by regression to a less mature level of functioning.

Symptomatology. Symptoms manifested in childhood do not necessarily carry the same significance they do in adult life, where typical symptom complexes lead to specific diagnoses. The presenting symptoms of immature individuals are much too unstable to provide reliable criteria for purposes of assessment; in fact, the child does not maintain a stable level of functioning in any area, at any time. Instead, the assessment of child psychopathology hinges on one crucial variable, specifically, the child's capacity to move forward in progressive stages until maturation has been achieved, his personality is sufficiently integrated, and he has adapted successfully to the social community. By the same token, emotional upsets become diagnostically and prognostically significant when they exert an adverse effect on the child's overall development—whether it is slowed up, reversed, or brought to a standstill.

Clearly, the assessment of psychopathology in childhood would become more meaningful if developmental norms were developed for all the parameters of the personality and attention were redirected from symptomatology to the child's position on the development scale. In that event, concern would center, more appropriately, on drive, ego, and superego development; on the structure of the personality, i.e., the stability of the boundaries between id, ego, and superego; and on the child's modes of functioning, i.e., evidence that primary thought processes have begun to give way to secondary thought processes, of progress from the pleasure principle to the reality principle. Considered within this frame of reference, it becomes apparent that the pathogenic impact of hereditary factors will depend, in large measure, on the developmental influences with which they interact. Similarly, organic defects, i.e., body malformations, may give rise to a wide range of psychological consequences, depending on the child's environmental circumstances and mental equipment. In brief, although any of the elements elicited in the assessment of child psychopathology may be identical by definition, there

may be wide differences in the significance attached to such elements in different personality settings. The fact is that indications of possible psychopathology in childhood cannot be properly evaluated if they are viewed in isolation or according to preconceived, rigid standards and criteria. Rather, they must be considered in relation to the child's total functioning and, more specifically, in terms of their potential effect on his development.

Personality Disorders in Childhood

Definition. Personality disorders in children represent relatively fixed pathological trends in personality development and functioning which have become a way of life more or less. According to the *Diagnostic and Statistical Manual* of the American Psychiatric Association (A.P.A.), "These disorders are characterized by developmental defects or pathological trends in the personality structure, with minimal subjective anxiety, and little or no sense of distress." The *Manual* further states that most frequently the personality disorder finds expression in a life-long pattern of pathological behavior, rather than mental or emotional symptoms.

Personality disorders are divided into three main categories: personality pattern disturbances, personality trait disturbances, and sociopathic personality disturbances. In this section personality pattern disturbances and personality trait disturbances will be discussed. Sociopathic personality disturbances are discussed elsewhere in this area.

Personality pattern disturbances are deep-seated disturbances; as such, their inherent structure can rarely be altered by therapy. At the same time, however, prolonged therapy may lead to an improvement in functioning, even though basic changes in personality structure occur only very infrequently. In the A.P.A. *Manual*, the classification of personality trait disturbance applies "to individuals who are unable to maintain their emotional equilibrium and independence under minor or major stress because of disturbances in emotional development." Some individuals are so classified because their personality pattern disturbance is closely related to the "fixation and exaggeration of certain character and behavior patterns; others, because their behavior is a regressive reaction due to environmental or endopsychic stress." This diagnostic classification is applied only when basic maldevelopment of personality is the crucial distinguishing factor, and the neurotic features, such as phobia, are relatively insignificant.

General considerations

Clinical features. Children with personality disorders solve their conflicts simply by changing their personality. This does not cause subjective feelings of discomfort unless they are confronted with the harsh realities of life, at which time they are forced to realize that their adaptive capacities are inade-

quate. In general, then, on superficial examination, the mode of behavior of children with personality trait disturbances will appear to be appropriate under normal conditions. When these children are under stress, however, they are unable to maintain their emotional equilibrium. Pathological personality traits then emerge as a reflection of their underlying disturbance.

Etiology. As pointed out earlier, clinical syndromes in childhood are shaped by age and developmental status, level of personality organization, and the nature and quality of the child's interaction with his environment. Unfortunately, at the present stage of our knowledge, it is impossible to postulate an etiological schema for personality disorders in childhood which will have taken all of these variables into account, and in so doing be conceptually and theoretically adequate and universally accepted.

A major impediment to our efforts in this connection stems from the instability of symptoms and reactions in childhood. It is not difficult to recognize that the child is in conflict with his environment at a given point in his development. However, criteria have not yet been developed which would permit us to predict the subsequent fate of this conflict, i.e., whether it will develop into an internal conflict or a personality disorder. The personality disorders—those psychopathological problems in children which are neither neurotic nor reactive, and which represent relatively fixed trends in personality development and personality functioning—are an area of particular concern and have given rise to considerable speculation. This concern is understandable in light of the fact that these disorders are considered to represent a more or less fixed way of life, largely because of the fact that they are accompanied by minimal subjective anxiety which, in turn, will obviously have an adverse influence on treatment efforts and prognosis.

Personality pattern disturbance. The official A.P.A. definition stresses that personality pattern disturbances in adults can rarely, if ever, be altered in their inherent structures by any form of therapy. Perhaps this accounts for the fact that most child psychiatrists hesitate to affix this diagnostic label to a troubled child. Yet careful long term studies have proven conclusively that this diagnostic classification may be justified in children. There are four types of personality pattern disturbance.

Inadequate personality. Although on examination they do not appear to be grossly deficient physically or mentally, according to the A.P.A. definition, adults in this category have an inadequate response to intellectual, emotional, social, and physical demands and display poor adaptability, ineptness, poor judgment, lack of physical and emotional stamina, and social incompatibility. Admittedly, the applicability of a definition as inclusive as this one to personality disorders in childhood is questionable. It is generally agreed that, even if a child does have this

syndrome, it will have less impact on him than it would on an adult so classified. More important, however, is the fact that criteria such as "inadequate response to intellectual and emotional demands" and "social incompatibility" clearly fail to recognize that the developing child has limited responsibilities and freedom. Under these circumstances, a diagnosis of "inadequate personality" would be difficult to substantiate; in any event, it is made only rarely.

Schizoid personality. Isolation is the most prominent symptom of the children in this group. They are further characterized by an inability to form close relationships with others, an inability to express "normal" feelings of aggression, and, in general, a tendency to withdraw emotionally from the environment. Typically, these children are quiet, shy, obedient, sensitive, and retiring. Frequently, they become more withdrawn and introverted at puberty, and sometimes they become eccentric. Many authors have pointed out that children with schizoid personalities show a marked infantilism, so that even their attempts to meet the ordinary problems of childhood evoke feelings of frustration which, in turn, give rise to poorly handled hostility. Fantasy becomes a common refuge. Most of these children grow up to be isolated adults; some develop psychotic episodes.

Etiology. The specific factors which produce this mode of behavior have not been clearly delineated. However, the available data do permit some generalizations. The histories of these patients point up their life-long isolation from parents, siblings, and others; and, in addition, there is a strong possibility that this pattern may be constitutionally determined. Apart from such considerations, however, almost without exception the parents of such children are themselves without close relationships, despite a facade of sociability. Usually, despite vehement protests to the contrary, these parents also manifest a marked ambivalence toward their child; they attach great importance to his physical care but are incapable of providing him with emotional warmth or acceptance.

Treatment. With therapy, such children may develop some warmth and a social facade, but, almost invariably, they return to their solitary activities with relief. The more severe cases may develop a psychotic reaction in adolescence under the stress of phase-specific tasks.

Cyclothymic personality. Adult cyclothymic personalities are characterized by "frequently alternating moods of elation and sadness, stimulated apparently by internal factors rather than external events." However, this diagnosis is almost never applied to a child. Mood changes in a child are influenced by parental attitudes, the family milieu, and peer relationships. If parents reward or praise the child, he feels happy; if they are chronically critical, he is depressed.

With regard to adults in this category, the A.P.A. *Diagnostic Manual* states that such persons demon-

strate "an outgoing adjustment to life situations, an apparent personal warmth, friendliness and superficial generosity, an emotional reaching out to the environment, and a ready enthusiasm for competition." It may be speculated that relatively minor events in the environment may precipitate a marked shift of these attitudes to feelings of sadness and depression when these events are unconsciously related to early childhood traumata.

It has been suggested that children who are subjected to the chronic disapproval of their parents may be predisposed to the development of a cyclothymic personality. At first glance, they appear mature, happy, and active. In fact, they are extremely sensitive, react with tears or depression when they are punished, and reveal marked mood variations, alternating between happiness and sadness with minimal stimuli. Although these features would seem to provide a foundation for the development of a cyclothymic personality in later life, not all children with these characteristics develop this disorder.

Etiology. The basic pathology stems from a conflict between a severe, punitive superego and powerful primitive unconscious impulses. When the superego is in ascendancy, the child is depressed and preoccupied with thoughts of self-depreciation and self-recrimination. Early childhood traumata, such as desertion, precipitate hostility which is turned inward and is manifested clinically as depression. As pointed out above, this clinical picture will not emerge with any clarity in the child whose emotional expressions will depend on his parents' attitudes toward him. Nor is the presence of such symptoms in childhood a reliable indication of the subsequent development of a cyclothymic personality; the fluidity of developmental processes in childhood prevents such a prediction.

Treatment. Treatment is necessarily intensive and should involve the parents, whose attitudes and care have much to do with the child's personality development and modes of behavior. Thus, child therapy becomes family therapy; understanding of the dynamics which underlie the child's problem must include an understanding of the family dynamics.

Paranoid personality. Many of the elements described above in connection with the schizoid personality are present in this syndrome, coupled with an exquisite sensitivity in interpersonal relations. Suspiciousness, mistrust, envy, extreme jealousy, and stubbornness are characteristic. Most marked is the tendency toward projection, a mechanism of defense by which one's own internal inadequacies and immaturities are attributed to others. This mechanism operates unconsciously and, although it is very common in children, is not so highly systematized in the early stages of development as it is in adults.

Etiology. Projection offers the child a means of ridding himself of uncomfortable feelings of inadequacy. This does not mean that the child who projects is going to develop a paranoid personality—

whether he blames his peers for being poor sports because he himself is a bad athlete or a "sore loser," blames his teacher for his failing grades, or accuses others of attacks he alone has provoked. The difficulties inherent in the accurate prediction of future psychopathology in the early years of life have been emphasized throughout this section. The child's extreme sensitivity may be due, for example, to an unusual constitutional sensitivity of the ego, although it will certainly be enhanced by a sense of insecurity and inadequacy and by the turbulent, suspicious, distrustful attitudes of disturbed parents.

Treatment. The goal of treatment is to strengthen the child's confidence, sense of security, and safety; to help him to develop appropriate reality testing; and, of course, to ameliorate family pathology. Treatment is always difficult; it is not always successful.

Personality trait disturbances. When there have been distortions in personality formation, various unhealthy modes of behavior may appear under stress, which are labeled personality trait disturbances. The *Diagnostic and Statistical Manual* states that "This classification will be applied only to cases of personality disorder in which the neurotic features (such as anxiety, conversion, phobia, etc.) are relatively insignificant, and the basic personality maldevelopment is the crucial distinguishing factor." Personality trait disturbances fall into three main groups.

Emotionally unstable personality. Once again, the fluidity of development precludes the use of this diagnosis with children. Nor is it used frequently with reference to adults, primarily because it is defined only vaguely and because the symptoms identified with this syndrome are relatively common. In brief, individuals included in this category react with extreme excitement, albeit ineffectively, in stress situations. Because of strong and poorly controlled hostility, guilt, and anxiety, relationships with other people in the environment are consistently undermined by fluctuating emotional attitudes.

Passive-aggressive personality. This category includes three types of reaction: passive-dependent, passive-aggressive, and aggressive. The underlying psychopathology is the same for each, and the three syndromes occur interchangeably. An anxiety reaction is almost always a concomitant in the clinical picture.

Passive-dependent type. Dependence on one's parents is normal during early childhood. Thus, this diagnosis is applied to those children whose dependency needs exceed "normal" limits. Such a child appears helpless and indecisive, clings to others, and obviously is neither autonomous nor independent to the degree considered healthy for his age or stage of development. Typically, these children were overprotected by parents who, however, often have mixed reactions about their child, encourage a helpless and clinging attitude, and inhibit the child's development of independence because of their own guilt feelings. Treatment is designed to facilitate the healthy matu-

ration of the child, of course, but an equally essential goal is the correction of unhealthy parental attitudes toward the child.

Passive-aggressive type. This clinical picture occurs most frequently in children. Passive obstructionism, inefficiency, procrastination, stubbornness, and pouting are hallmarks of this type of aggression. This behavior is seen in many children as an expression of resentment, invoked by excessive parental demands. The "normal" parent expects the child to resent his demands at times and is prepared to accept some of the child's hostility. On the other hand, if any overt expression of hostility is deemed unacceptable by the parent, the child may develop more subtle rebellious behavior, particularly if the parent expresses his objections to the child's hostility by criticizing or punishing him excessively. A classic reaction to such parental behavior is the child who dawdles endlessly over meals, because the child is well aware that this type of passive-aggressive behavior will not elicit the punishment or disapproval he has learned to associate with expressions of open hostility. Not unexpectedly, the goal of treatment is to help the child express his resentments and hostilities openly and in more acceptable ways. At the same time, his parents are made aware of their suppressive, critical attitudes and are helped to correct them.

Aggressive type. Such behavior is not to be confused with delinquent reactions. As pointed out above, the underlying dependency of the passive-aggressive child is strong and is enforced by ambivalent parental attitudes, especially on the part of the mother. When such a child is frustrated repeatedly, he may display overt and angry behavior, which incidentally may be antisocial. On the other hand, quite often it seems that the child's excessive demands could not conceivably be satiated, that his frustration is self-inflicted and inevitable. In either case, irritability, temper tantrums, destructive behavior, and, above all, a fierce resentment which leads him to strike out at the environment characterize this syndrome. Here, again, treatment focuses not only on helping the child develop healthier modes of expression and adequate gratifications, but also on correcting the parents' pathological attitudes toward the child.

Compulsive personality. The pathology manifested by a good, conforming child usually escapes recognition. Excessive rigidity and conformity, overconscientiousness, and inhibition of emotional expression are marked in these children, who are so well behaved they become mature, or pseudomature, too early. Like adults, these children show an obsessive concern with adherence to standards of conscience or conformity and may have an inordinate capacity for work without the usual capacity for relaxation.

Etiology. Such children are fixated at the anal stage of libidinal development. The resulting immaturities are countered by a punitive superego which is so strict that the child appears to be unusually well behaved, worrisome, inhibited, and organized. In light

of the fact that the parents of such children are compulsive, driving, perfectionistic individuals with very high standards, it has been speculated that this type of personality is hereditary.

Treatment. Treatment seeks to develop a more balanced intrapsychic relationship between instinctual expressions, coping mechanisms, and the dictates of the superego. Parents' attitudes must be altered as well, for one should not underestimate the influence that the parental expectations and image of a good, well behaved, conscientious child may have had on the child's personality formation.

G.A.P. Classification of Disorders in Children

The Committee on Child Psychiatry of the Group for the Advancement of Psychiatry (G.A.P.) has recommended that the classification of personality disorders in childhood remain descriptive until the whole area of chronic or fixed trends in total personality structure has been defined more clearly. The Committee has thus expressed its awareness of the deficiencies in current classifications and the fact that they are basically unsuited to child psychiatry. The Committee has also suggested other categories, in the hope that they may prove more realistic and have greater clinical validity than the categories listed in the A.P.A. *Manual*. The categories recommended by G.A.P. are listed below and are largely self-explanatory. This proposed classification has not been universally accepted; nevertheless, it represents a major step forward. The classification is as follows: (1) anxious personality; (2) compulsive personality; (3) hysterical personality; (4) overly dependent personality; (5) oppositional personality; (6) overinhibited personality; (7) overindependent personality; (8) isolated personality (replacing schizoid personality); (9) mistrustful personality (replacing paranoid personality); (10) tension discharge disorders: (a) impulse-ridden personality and (b) neurotic personality disorder; (11) sociosyntonic personality disorder; (12) sexual deviations; (13) other personality disorders.

Anxious personality. These children are chronically tense and apprehensive over new situations. Their anxiety is not so crippling, however, as the anxiety experienced in anxiety neurosis.

Compulsive personality. These children are characterized by excessive orderliness, cleanliness, and conformity. Their personalities are rigid and inflexible, with occasional obsessive thoughts and compulsive rituals.

Hysterical personality. More girls than boys are included in this group which shows tendencies toward overly dramatic, flamboyant, overly labile, overly affective, overly suggestible, coy, and seductive behavior. Symptom formation of conversion or dissociative nature may occur with stress.

Overly dependent personality. Children in this group are chronically helpless, clinging, and overly dependent and have difficulty in achieving independent initiative. Included here are some children formerly classified as passive-aggressive, passive-dependent, immature, or unstable personalities.

Oppositional personality. These children show their aggressiveness by oppositional behavior of a passive character, which

often has aggressive implications. Typically, they use negativism, stubbornness, and procrastination and are often quite provocative. These children were previously in the passive-aggressive category.

Overly inhibited personality. On superficial examination, these children manifest passivity, shyness, motor inhibition, and marked constriction of personality functions. They differ from the schizoid (isolated) personalities, however, in that they have a deep desire for warm meaningful relationships.

Overly independent personality. These children show a chronically ebullient, active behavior, with a need to rush toward independence and concomitant difficulty in accepting limits. Their behavior is pseudoprecocious, for, in general, they have a positive attitude.

Isolated personality (replacing schizoid). These children tend to show distant, detached, cold, or withdrawn attitudes. They are frequently isolated, seclusive, and unable to form warm and meaningful attachments.

Mistrustful personality (replacing paranoid). This disorder, rare in childhood and more common during adolescence, is characterized by suspiciousness, intense distrust of others, and rigidity in thinking.

Tension discharge disorder. These children exhibit chronic behavioral patterns involving aggressive and sexual impulses. As a result, they are in constant conflict with society, for they act out these impulses in an antisocial or destructive fashion. Included here are the former designations of antisocial personality, sociopathic personality, and psychopathic personality. In addition, children who were previously diagnosed as acting out or as manifesting conduct disorders and behavior disorders fall into this category. This category includes two major subdivisions:

Impulse-ridden personality. These children have a low frustration tolerance and shallow relationships with adults. They have poor control of their impulses, little anxiety and internalized guilt, and defective superego formation.

Neurotic personality disorder. The behavior of these children is similar to that of the impulse-ridden personalities, described above, with two exceptions: they act out tension resulting from conflict of a neurotic origin, and there is evidence of conscience formation.

Sociosyntonic personality disorder. This category consists of two groups. The first exhibits aggressive antisocial personality trends which, although they deviate from the standards of society, are consonant with their environment (the dyssocial category). The second group includes children from subcultures, such as isolated rural settings, who may have hallucinatory experiences, embrace voodoo beliefs, etc.

Sexual deviations. These children show chronic, relatively fixed sexual deviations. Usually, this classification is used only with adolescents and applies only in those cases where the deviation is pervasive and chronic.

Other personality disorders. Included here are personality disorders not listed under other headings, such as cyclothymic personality.

In summary, when the progressive integration of personality and the establishing of structural boundaries between id, ego, and superego are impaired by the conscious and unconscious parental attitudes toward the child, psychopathology will result. Constitutional givens are an important factor. The particular manifest continuation of specific attitudes singles out personality types. Precipitate reaction formations, related to early infantile stages of development, determine character traits. Treatment is not restricted to the child but involves the parents or family as well. The most effective type of treatment by far, for these clinical syndromes, is the psychoanalytically oriented approach.

Suggested Cross References

See the editors' introduction to this area for further comments regarding nomenclature in child psychiatry. For further information regarding personality disorders, see Chapters 25, 26, 27, and 28 in Area F, on the psychiatric disorders of adults. Area C, on current theories of personality and psychopathology, contains a more detailed description of the psychoanalytic concept of personality development as well as discussions of some alternate viewpoints regarding this subject.

stated that "children now love luxury. They have bad manners and contempt for authority. They show disrespect to their elders and love to chatter in place of exercise." Shakespeare had a character say in a play, "I would that man could forego the pleasure of life from four and ten to one and twenty, when youth does nothing but fight, drink, and get wench with child."

Modern concepts of delinquency suggest that children who are called delinquent are ill primarily in terms of society, in their inability to conform to the social milieu. Since the social and cultural milieu is influenced by many factors—education, radio, television, socioeconomic levels, minority racial groups, poverty, war and threat of war, civil rights movements, immigration, and many others—it is not possible to give precise definitions of delinquent behavior. In addition, one can view our states and cities as a wide variety of legal systems, attempting to evaluate, modify, and contain individual and group behavior. What is viewed as antisocial behavior in one city may not be viewed identically in another city or may be viewed differently by the same city officials over a period of time. As an illustration, an adolescent Negro boy may be arrested and sent to a reformatory for participating in a restaurant sit-in, and, after the local laws are changed, essentially the same behavior would go unnoticed. Laws tend to reflect current morality to a greater or lesser extent, and children are caught up in intense personal conflicts in our rapidly shifting and changing culture. Clearly, some fail to adapt to the various pressures as well as others. We can speak of two types of sociopathic patterns: (1) antisocial reaction—characteristic of children and adolescents who are always in trouble, who seem not to profit from experience or punishment, and who have no loyalties to persons other than themselves—and (2) dyssocial reaction—characteristic of children and adolescents who have been brought up in amoral or immoral families or institutions and who have identified with strong loyalties to a criminal element, for example, children whose parents are gypsies or habitual criminals.

It should be noted that both antisocial and dyssocial reactions are subsumed in the standard nomenclature of the American Psychiatric Association under the larger heading of sociopathic personality disturbance, this latter grouping being a category in which individuals "are ill primarily in terms of society and of conformity with the prevailing cultural milieu, and not only in terms of personal discomfort and relations with other individuals."

Epidemiology

It is generally accepted that the incidence of antisocial reactions varies from about 2 per cent to about 7 per cent of the childhood population. There are more than 3,000 juvenile courts in this country, and modern policies of juvenile probation programs permit many

41.4 **SOCIOPATHIC PERSONALITY DISORDERS. I: ANTISOCIAL AND DYSSOCIAL REACTIONS**

ROBERT L. STUBBLEFIELD, M.D.

Definitions

The concept of juvenile delinquency has been known to man for many centuries. Socrates in 500 B.C.

officers, after appropriate education and inservice instruction, to make quick decisions in the community, so that many children are not booked and identified by a formal court procedure. The reporting systems must be studied at the probation officer level in order to obtain accurate figures for study.

In boys the major offenses are truancy, stealing, fire setting, vandalism, and cruelty to animals and humans; in girls the major offenses are stealing, shoplifting, and sexual promiscuity. It is accepted generally that the incidence is higher in males; it is higher in low income, minority, and culturally deprived groups; and it rises with industrialization and urbanization of a population. Distribution and incidence studies should be done in individual cities and regions to plan reasonable control programs in the classical public health sense of the phrase, since it is difficult to generalize about findings from one city to develop a public crime and delinquency prevention program in another city.

Etiology and Pathology

The general physician and psychiatrist should consider a number of diagnostic possibilities in evaluating the possible etiology of antisocial and dyssocial behavior. He should think in terms of conditions that must be met in order to explain the maladaptive behavior pattern of the individual child. Any illness or defect that contributes to misperception of the external environment or the inability to identify with healthy personalities or the inability to inhibit hyper-aggressive or hyperlibidinal behavior may contribute to the delinquent behavior pattern. This pattern may be caused by mental retardation, epilepsy, brain damage, hyperkinesis, compulsion neurosis, childhood psychosis, and affect deprivation to name a few.
